Cerebral edema is an extremely serious complication of hepatic encephalopathy that responds poorly to measures such as corticosteroid administration and osmotic diuresis. Monitoring intracranial pressure can be useful in preventing severe cerebral edema, in maintaining cerebral perfusion pressure, and in establishing the suitability of a patient for liver transplantation. Controlled trials have shown a worsened outcome of fulminant hepatic failure in patients treated with corticosteroids.

Temporary liver support continues to be evaluated as a bridge for the patient with liver failure to liver transplantation or regeneration. Nonbiologic systems, essentially a form of liver dialysis with an albumin-containing dialysate, and biologic liver support devices that involve perfusion of the patient's blood through a cartridge containing liver cell lines or porcine hepatocytes can remove some toxins, improve serum biochemical abnormalities, and, in some cases, improve neurologic function, but there has been little evidence of improved survival, and few children have been treated.

Orthotopic liver transplantation can be lifesaving in patients who reach advanced stages (III, IV) of hepatic coma. Reduced-size allografts and living donor transplantation have been important advances in the treatment of infants with hepatic failure. Partial auxiliary orthotopic or heterotopic liver transplantation is successful in a small number of children, and in some cases it has allowed regeneration of the native liver and eventual withdrawal of immunosuppression. Orthotopic liver transplantation should not be done in patients with liver failure and neuromuscular dysfunction secondary to a mitochondrial disorder because progressive neurologic deterioration is likely to continue after transplantation.

PROGNOSIS

Children with acute hepatic failure fare better than adults. Improved survival can be attributed to careful intensive care and if necessary liver transplantation. In the largest prospective study from the Pediatric Acute Liver Failure Study Group, 709 children were assessed at 21 days: 50.3% of patients survived with supportive care alone, 36.2% survived after liver transplantation, and 13.4% died. A scoring system based on peak values of total serum bilirubin, PT, and plasma ammonia concentration predicted transplant-free survival. Prognosis varies considerably with the cause of liver failure and stage of hepatic encephalopathy. Survival rates with supportive care may be as high as 90% in acetaminophen overdose and with fulminant hepatitis A. By contrast, spontaneous recovery can be expected in only approximately 40% of patients with liver failure caused by the idiopathic form of acute liver failure or an acute onset of Wilson disease. In patients who progress to stage IV coma (see Table 364-1), the prognosis is extremely poor. Brainstem herniation is the most common cause of death. Major complications such as sepsis, severe hemorrhage, or renal failure increase the mortality. The prognosis is particularly poor in patients with liver necrosis and multiorgan failure.

Age <1 yr, stage 4 encephalopathy, an INR >4, and the need for dialysis before transplantation are associated with increased mortality. Pretransplantation serum bilirubin concentration or the height of hepatic enzymes is not predictive of posttransplantation survival. A plasma ammonia concentration >200 μmol/L is associated with a 5-fold increased risk of death.

Children with acute hepatic failure are more likely to die while on the waiting list compared to children with other diagnoses. Owing to the severity of their illness, the 6 mo post–liver transplantation survival of approximately 75% in most studies is significantly lower than the 90% achieved in children with chronic liver disease. Patients who recover from fulminant hepatic failure with only supportive care do not usually develop cirrhosis or chronic liver disease. Aplastic anemia occurs in approximately 10% of children with the idiopathic form of fulminant hepatic failure and is often fatal.

Chapter 365

Cystic Diseases of the Biliary Tract and Liver

Frederick J. Suchy

Cystic lesions of liver may be initially recognized during infancy and childhood (Table 365-1). Hepatic fibrosis can also occur as part of an associated developmental defect (Table 365-2). Cystic renal disease is usually associated and often determines the clinical presentation and prognosis. Virtually all proteins encoded by genes mutated in combined cystic diseases of the liver and kidney are at least partially localized to primary cilia in renal tubular cells and cholangiocytes.

CHOLEDOCHAL CYSTS

Choledochal cysts are congenital dilatations of the common bile duct that can cause progressive biliary obstruction and biliary cirrhosis. Cylindrical (fusiform) and spherical (saccular) cysts of the extrahepatic ducts are the most common types. Segmental or diffuse dilation can be observed. A diverticulum of the common bile duct or dilation of the intraduodenal portion of the common duct *(choledochocele)* is a variant. Cystic dilation of the intrahepatic bile ducts may be associated with a choledochal cyst or Caroli disease.

The pathogenesis of choledochal cysts remains uncertain. Some reports suggest that junction of the common bile duct and the pancreatic duct before their entry into the sphincter of Oddi might allow reflux of pancreatic enzymes into the common bile duct, causing inflammation, localized weakness, and dilation of the duct. It also has been proposed that a distal congenital stenotic segment of the biliary tree leads to increased intraluminal pressure and proximal biliary dilation. Other possibilities are that choledochal cysts represent malformations of the common duct or that they occur as part of the spectrum of an infectious disease that includes neonatal hepatitis and biliary

Table 365-2 Syndromes Associated with Congenital Hepatic Fibrosis

SYNDROME	FEATURES
Jeune syndrome	Asphyxiating thoracic dystrophy, with cystic renal tubular dysplasia and congenital hepatic fibrosis (15q13)
Joubert syndrome	Oculo-encephalo-hepato-renal *(AH11, HPHP1)*
COACH syndrome	Cerebellar vermis hypoplasia, oligophrenia, congenital ataxia, ocular coloboma, and hepatic fibrosis *(MKS3, CC2D2A, RPGRIP1L)*
Meckel syndrome type 1	Cystic renal dysplasia abnormal bile duct development with fibrosis, posterior encephalocele, and polydactyly (13q13, 17a21, 8q24)
Carbohydrate-deficient glycoprotein syndrome type 1b	Phosphomannose isomerase 1 deficiency (PMI)
Ivemark syndrome type 2	Autosomal-recessive renal-hepatic-pancreatic dysplasia
Miscellaneous syndromes	Intestinal lymphangiectasia, enterocolitis cystic Short rib (Beemer-Langer) syndrome Osteochondrodysplasia

From Suchy FJ, Sokol RJ, Balistreri WF, editors: Liver disease in children, *ed 3, New York, 2007, Cambridge University Press, p. 931.*

atresia. Consistent with this theory, reovirus RNA has been detected in liver and biliary tissues of some infants with choledochal cysts.

Approximately 75% of cases appear during childhood. The infant typically presents with cholestatic jaundice; severe liver dysfunction including ascites and coagulopathy can rapidly evolve if biliary obstruction is not relieved. An abdominal mass is rarely palpable. In an older child, the **classic triad** of abdominal pain, jaundice, and mass occurs in <33% of patients. Features of acute cholangitis (fever, right upper quadrant tenderness, jaundice, leukocytosis) may be present. The diagnosis is made by ultrasonography; choledochal cysts have been identified prenatally using this technique. Magnetic resonance cholangiography is useful in the preoperative assessment of choledochal cyst anatomy.

The **treatment of choice** is primary excision of the cyst and a Roux-en-Y choledochojejunostomy. Simple drainage into the small bowel is less satisfactory owing to a risk of development of carcinoma in the residual cystic tissue. The postoperative course can be complicated by recurrent cholangitis or stricture at the anastomotic site.

Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease (ARPKD) manifests predominantly in childhood (see Chapter 521.2). Bilateral enlargement of the kidneys is caused by a generalized dilation of the collecting tubules. The disorder is invariably associated with congenital hepatic fibrosis and various degrees of biliary ductal ectasia that are discussed in detail later.

The polycystic kidney and hepatic disease 1 *(PKHD1)* gene, mutated in ARPKD, encodes a protein that is called fibrocystin/polyductin, which is localized to cilia on the apical domain of renal collecting cells and cholangiocytes. The primary defect in ARPKD may be ciliary dysfunction related to the abnormality in this protein. Fibrocystin/polyductin appears to have a role in the regulation of cellular adhesion, repulsion, and proliferation and/or the regulation and maintenance of renal collecting tubules and bile ducts, but its exact role in normal and cystic epithelia remains unknown. Kidney and liver disease are independent and variability in severity and not explainable by type of *PKHD1* mutation. Phenotypic variability among affected siblings suggests importance of modifier genes as well as possibly environmental influences.

In ARPKD, the cysts arise as ectatic expansions of the collecting tubules and bile ducts that remain in continuity with their structures of origin. ARPKD normally presents in early life, often shortly after birth, and is generally more severe than autosomal dominant polycystic kidney disease (ADPKD). Fetal ultrasound may visualize large echogenic kidneys, also described as "bright," with low or absent amniotic fluid (oligohydramnios). However, in many instances the features of ARPKD are not visualized on sonogram until the 3rd trimester or after birth.

Patients with ARPKD can die in the perinatal period owing to renal failure or lung dysgenesis. The kidneys in these patients are usually markedly enlarged and dysfunctional. Respiratory failure can result from compression of the chest by grossly enlarged kidneys, from fluid retention, or from concomitant pulmonary hypoplasia (see Chapter 515.2). The clinical pathologic findings within a family tend to breed true, although there has been some variability in the severity of the disease and the time for presentation within the same family. In patients surviving infancy because of a milder renal phenotype, liver disease may be a prominent part of the disorder. The liver disease in ARPKD is related to congenital malformation of the liver with varying degrees of periportal fibrosis, bile ductular hyperplasia, ectasia, and dysgenesis. Initial symptoms are liver related in approximately 26% of patients. This can manifest clinically as variable, cystic dilation of the intrahepatic biliary tree with congenital hepatic fibrosis. Congenital hepatic fibrosis and Caroli disease likely result from an abnormality in remodeling of the embryonic ductal plate of the liver. *Ductal plate malformation* refers to the persistence of excess embryonic bile duct structures in the portal tracts.

Variable abnormalities of bile ducts (irregular dilation, proliferation, cysts) and portal fibrosis can also be associated with Meckel syndrome,

trisomy 17-18, tuberous sclerosis, and asphyxiating thoracic dystrophy (see Table 365-2).

Cystic Dilation of the Intrahepatic Bile Ducts (Caroli Disease)

Congenital saccular dilation can affect several segments of the intrahepatic bile ducts; the dilated ducts are lined by cuboidal epithelium and are in continuity with the main duct system, which is usually normal. Choledochal cysts have also been associated with Caroli disease. Bile duct dilation leads to stagnation of bile and formation of biliary sludge and intraductal lithiasis.

There is a marked predisposition to ascending cholangitis which may be exacerbated by calculus formation within the abnormal bile ducts.

Affected patients usually experience symptoms of acute cholangitis as children or young adults. Fever, abdominal pain, mild jaundice, and pruritus occur, and a slightly enlarged, tender liver is palpable. Elevated alkaline phosphatase activity, direct-reacting bilirubin levels, and leukocytosis may be observed during episodes of acute infection. In patients with Caroli disease, clinical features may be the result of a combination of recurring bouts of cholangitis, reflecting the intrahepatic ductal abnormalities and portal hypertensive bleeding resulting from hepatic fibrosis. Ultrasonography shows the dilated intrahepatic ducts, but definitive diagnosis and extent of disease must be determined by percutaneous transhepatic, endoscopic, or magnetic resonance cholangiography.

Cholangitis and sepsis are treated with appropriate antibiotics. Calculi can require surgery. Partial hepatectomy may be curative in rare cases in which cystic disease is confined to a single lobe. The prognosis is otherwise guarded, largely owing to difficulties in controlling cholangitis and biliary lithiasis and to a significant risk for developing cholangiocarcinoma. ARPKD patients with recurrent cholangitis or complications of portal hypertension may require combined liver-kidney transplant.

Congenital Hepatic Fibrosis

Congenital hepatic fibrosis is usually associated with ARPKD and is characterized pathologically by diffuse periportal and perilobular fibrosis in broad bands that contain distorted bile duct–like structures and that often compresses or incorporate central or sublobular veins (see Table 365-2). Irregularly shaped islands of liver parenchyma contain normal-appearing hepatocytes. Caroli disease and choledochal cysts are associated. Most patients have renal disease, mostly autosomal recessive polycystic renal disease and rarely nephronophthisis. Congenital hepatic fibrosis also occurs as part of the **COACH syndrome** (*c*erebellar vermis hypoplasia, *o*ligophrenia, congenital *a*taxia, *c*oloboma, and *h*epatic fibrosis). Congenital hepatic fibrosis has been described in children with a congenital disorder of glycosylation caused by mutations in the gene encoding phosphomannose isomerase (see Chapter 87.6).

Several different forms of congenital hepatic fibrosis have been defined clinically: portal hypertensive (most common) cholangitic, mixed, and latent. The disorder usually has its onset in childhood, with hepatosplenomegaly or with bleeding secondary to portal hypertension. In a recent study, splenomegaly, as a marker for portal hypertension, developed early in life and was present in 60% of children younger than 5 yr of age.

Cholangitis can occur in patients, as these patients have abnormal biliary tracts even without Caroli disease. Hepatocellular function is usually well preserved. Serum aminotransferase activities and bilirubin levels are usually normal in the absence of cholangitis and choledocholithiasis; serum alkaline phosphatase activity may be slightly elevated. The serum albumin level and prothrombin time are normal. Liver biopsy is rarely required for diagnosis, particularly in patients with obvious real disease.

Treatment of this disorder should focus on control of bleeding from esophageal varices and aggressive antibiotic treatment of cholangitis. Infrequent mild bleeding episodes may be managed by endoscopic sclerotherapy or band ligation of the varices. After more-severe hemorrhage, portacaval anastomosis can relieve portal hypertension. The prognosis may be greatly improved by a shunting procedure, but survival in some patients may be limited by renal failure.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ADPKD (see Chapter 521.3), a common inherited disease, affects 1 in 1,000 live births. It is characterized by progressive renal cyst development and cyst enlargement and an array of extrarenal manifestations. There is a high degree of intrafamilial and interfamilial variability in the clinical expression of the disease.

ADPKD is caused by mutation in 1 of 2 genes, *PKD1* or *PKD2*, which account for 85-90% and 10-15% of cases, respectively. The proteins encoded by these genes, polycystin-1 and polycystin-2, are expressed in renal tubule cells and in cholangiocytes. Polycystin-1 functions as a mechanosensor in cilia, detecting the movement of fluid through tubules and transmitting the signal through polycystin-2, which acts as a calcium channel.

Dilated, noncommunicating cysts are most commonly observed. Other hepatic lesions are rarely associated with ADPKD, including the ductal plate malformation, congenital hepatic fibrosis, and biliary microhamartomas (the von Meyenburg complexes). Approximately 50% of patients with renal failure have demonstrable hepatic cysts that are derived from, but not in continuity with, the biliary tract. The hepatic cysts increase with age. A recent imaging study showed that prevalence of hepatic cysts was 58% in patients 15-24 yr old. Hepatic cystogenesis appears to be influenced by estrogens. Although the frequency of cysts is similar in boys and girls, the development of large hepatic cysts is mainly a complication in girls. Hepatic cysts are often asymptomatic but can cause pain and are occasionally complicated by hemorrhage, infection, jaundice from bile duct compression, portal hypertension with variceal bleeding, or hepatic venous outflow obstruction from mechanical compression of hepatic veins, resulting in tender hepatomegaly and exudative ascites. Cholangiocarcinoma can occur. Subarachnoid hemorrhage can result from the associated cerebral arterial aneurysms.

Selected patients with severe symptomatic polycystic liver disease and favorable anatomy benefit from liver resection or fenestration. Combined liver-kidney transplantation may be required.

There is considerable evidence for a role of cyclic adenosine monophosphate in epithelial proliferation and fluid secretion in experimental renal and hepatic cystic disease. Several clinical trials in adults have shown that somatostatin analogs can blunt hepatic cyst expansion by blocking secretin-induced cyclic adenosine monophosphate generation and fluid secretion by cholangiocytes.

AUTOSOMAL DOMINANT POLYCYSTIC LIVER DISEASE

Autosomal dominant polycystic liver disease is a distinct clinical and genetic identity in which multiple cysts develop and are unassociated with cystic kidney disease. Liver cysts arise from but are not in continuity with the biliary tract. Girls are more commonly affected than boys, and the cysts often enlarge during pregnancy. Cysts are rarely identified in children. Cyst complications are related to effects of local compression, infection, hemorrhage, or rupture. Genes associated with autosomal dominant polycystic liver disease are *PRKCSH* and *SEC63*, which encode hepatocystin and Sec63, respectively. Hepatocystin is a protein kinase C substrate adK-H that is involved in the proper folding and maturation of glycoproteins. It has been localized to the endoplasmic reticulum. *SEC63* encodes a protein SEC63P, which is a component of the protein translocation machinery in the endoplasmic reticulum.

A solitary liver cyst (nonparasitic) rarely occurs in childhood. Abdominal distention and pain may be present, and a poorly defined right upper quadrant mass may be palpable. These benign lesions are best left undisturbed unless they compress adjacent structures or a complication occurs, such as hemorrhage into the cyst.

Chapter 366
Diseases of the Gallbladder

Frederick J. Suchy

ANOMALIES

The gallbladder is congenitally absent in approximately 0.1% of the population. Hypoplasia or absence of the gallbladder can be associated with extrahepatic biliary atresia or cystic fibrosis. Duplication of the gallbladder occurs rarely. Gallbladder ectopia may occur with a transverse, intrahepatic, left-sided, or retroplaced location. Multiseptate gallbladder, characterized by the presence of multiple septa dividing the gallbladder lumen, is another rare congenital anomaly of the gallbladder.

ACUTE HYDROPS

Table 366-1 lists the conditions associated with hydrops of the gallbladder.

Acute noncalculous, noninflammatory distention of the gallbladder can occur in infants and children. It is defined by the absence of calculi, bacterial infection, or congenital anomalies of the biliary system. The disorder may complicate acute infections and Kawasaki disease, but the cause is often not identified. Hydrops of the gallbladder may also develop in patients receiving long-term parenteral nutrition, presumably as a result of gallbladder stasis during the period of enteral fasting. Hydrops is distinguished from acalculous cholecystitis by the absence of a significant inflammatory process and a generally benign prognosis.

Affected patients usually have right upper quadrant pain with a palpable mass. Fever, vomiting, and jaundice may be present and are usually associated with a systemic illness such as streptococcal infection. Ultrasonography shows a markedly distended, echo-free gallbladder, without dilation of the biliary tree. Acute hydrops is usually treated conservatively with a focus on supportive care and managing the intercurrent illness; cholecystostomy and drainage are rarely needed. Spontaneous resolution and return of normal gallbladder function usually occur over a period of several wk. If a laparotomy is required, a large, edematous gallbladder is found to contain white, yellow, or green bile. Obstruction of the cystic duct by mesenteric adenopathy is occasionally observed. Cholecystectomy is required if the gallbladder is gangrenous. Pathologic examination of the gallbladder wall shows edema and mild inflammation. Cultures of bile are usually sterile.

Prolonged fasting	
Viral hepatitis	
Sepsis	
Henoch-Schönlein purpura	
Mesenteric adenitis	
Necrotizing enterocolitis	

CHOLECYSTITIS AND CHOLELITHIASIS

Acute acalculous cholecystitis is uncommon in children and is usually caused by infection. Pathogens include streptococci (groups A and B), Gram-negative organisms, particularly *Salmonella* and *Leptospira interrogans*. Parasitic infestation with *Ascaris* or *Giardia lamblia* may be found. Calculous cholecystitis may rarely follow abdominal trauma or burn injury or is associated with a systemic vasculitis, such as periarteritis nodosa.

Clinical features include right upper quadrant or epigastric pain, nausea, vomiting, fever, and jaundice. Right upper quadrant guarding and tenderness are present. Ultrasonography discloses an enlarged, thick-walled gallbladder, without calculi. Serum alkaline phosphatase activity and direct-reacting bilirubin levels are elevated. Leukocytosis is usual.

Patients may recover with treatment of systemic and biliary infection. Because the gallbladder can become gangrenous, daily ultrasonography is useful in monitoring gallbladder distention and wall thickness. Cholecystectomy is required in patients who fail to improve with conservative management. Cholecystostomy drainage is an alternative approach in a critically ill patient.

Cholelithiasis is relatively rare in otherwise healthy children, occurring more commonly in patients with various predisposing disorders (Table 366-2). In an ultrasonographic survey of 1570 children (ages 6-19 yr) the overall prevalence of gallstone disease was 0.13% (0.27% in female subjects). In children, >70% of gallstones are the pigment type, 15-20% are cholesterol stones, and the remainder are composed of a mixture of cholesterol, organic matrix, and calcium bilirubinate. Black pigment gallstones, composed mostly of calcium bilirubinate and glycoprotein matrix, are a frequent complication of chronic hemolytic anemias. Brown pigment stones form mostly in infants as a result of biliary tract infection. Unconjugated bilirubin is the predominant component, formed by the high β-glucuronidase activity of infected bile. Cholesterol gallstones are composed purely of cholesterol or contain >50% cholesterol along with a mucin glycoprotein matrix and calcium bilirubinate. Calcium carbonate stones have also been described in children.

Patients with hemolytic disease (including sickle cell anemia, the thalassemias, and red blood cell enzymopathies) and Wilson disease are at increased risk for black pigment cholelithiasis. In sickle cell disease, pigment gallstones can develop before age 4 yr and have been reported in 17-33% of patients 2-18 yr of age. Genetic variation in the promoter of uridine diphosphate-glucuronosyltransferase 1A1 (the [TA]7/[TA]7 and [TA]7/[TA]8 genotypes) underlies **Gilbert syndrome**, a relatively common, chronic form of unconjugated hyperbilirubinemia, and is a risk factor for pigment gallstone formation in sickle cell disease.

Table 366-2	Conditions Associated with Cholelithiasis

Treatment of childhood cancer	
Abdominal surgery	
Pregnancy	
Sepsis	
Genetic *(ABCB4, ABCG5/G8)* progressive familial intrahepatic cholestasis	
Cephalosporins	

Cirrhosis and chronic cholestasis also increase the risk for pigment gallstones. Sick premature infants may also have gallstones; their treatment is often complicated by such factors as bowel resection, necrotizing enterocolitis, prolonged parenteral nutrition without enteral feeding, cholestasis, frequent blood transfusions, and use of diuretics. Cholelithiasis in premature infants is often asymptomatic and may resolve spontaneously. Brown pigment stones are found in infants with obstructive jaundice and infected intra- and extrahepatic bile ducts. These stones are usually radiolucent, owing to a lower content of calcium phosphate and carbonate and a higher amount of cholesterol than in black pigment stones. MDR3 deficiency caused by *ABCB4* mutations) is a cholestatic syndrome related to impaired biliary phospholipid excretion. It is associated with symptomatic and recurring cholelithiasis. Patients may show intrahepatic lithiasis, sludge, or microlithiasis along the biliary tree.

Obesity has assumed an increasingly important role as a risk factor for cholesterol cholelithiasis in children, particularly in adolescent girls. Cholesterol gallstones are also found in children with disturbances of the enterohepatic circulation of bile acids, including patients with ileal disease and bile acid malabsorption, such as those with ileal resection, ileal Crohn disease, and cystic fibrosis. Pigment stones can also occur in these patients.

Cholesterol gallstone formation seems to result from an excess of cholesterol in relation to the cholesterol-carrying capacity of micelles in bile. Supersaturation of bile with cholesterol, leading to crystal and stone formation, could result from decreased bile acid or from an increased cholesterol concentration in bile. Other initiating factors that may be important in stone formation include gallbladder stasis or the presence in bile of abnormal mucoproteins or bile pigments that may serve as a nidus for cholesterol crystallization.

Prolonged use of high-dose ceftriaxone, a third-generation cephalosporin, has been associated with the formation of calcium-ceftriaxone salt precipitates *(biliary pseudolithiasis)* in the gallbladder. Biliary sludge or cholelithiasis can be detected in >40% of children who are treated with ceftriaxone for at least 10 days. In rare cases, children become jaundiced and develop abdominal pain; precipitates usually resolve spontaneously within several months after discontinuation of the drug.

Acute or chronic cholecystitis is often associated with gallstones. The acute form may be precipitated by impaction of a stone in the cystic duct. Proliferation of bacteria within the obstructed gallbladder lumen can contribute to the process and lead to biliary sepsis. Chronic calculous cholecystitis is more common. It can develop insidiously or follow several attacks of acute cholecystitis. The gallbladder epithelium commonly becomes ulcerated and scarred.

More than 50% of patients with gallstones have symptoms, and 18% present with a complication as the first indication of cholelithiasis, such as pancreatitis, choledocholithiasis or acute calculous cholecystitis. The most important clinical feature of cholelithiasis is recurrent abdominal pain, which is often colicky and localized to the right upper quadrant. An older child may have intolerance for fatty foods. Acute cholecystitis is characterized by fever, pain in the right upper quadrant, and often a palpable mass. Jaundice occurs more commonly in children than adults. Pain may radiate to an area just below the right scapula. A plain x-ray of the abdomen may reveal opaque calculi, but radiolucent (cholesterol) stones are not visualized. Accordingly, ultrasonography is the method of choice for gallstone detection. Hepatobiliary scintography is a valuable adjunct in that failure to visualize the gallbladder provides evidence of cholecystitis.

Cholecystectomy is curative. Laparoscopic cholecystectomy is routinely performed in symptomatic infants and children with cholelithiasis. Common bile duct stones are unusual in children, occurring in 2-6% of cases with cholelithiasis, often in association with obstructive jaundice and pancreatitis. Operative cholangiography should be done at the time of surgery, however, to detect unsuspected common duct calculi. Endoscopic retrograde cholangiography with extraction of common duct stones is an option before laparoscopic cholecystectomy in older children and adolescents.

Asymptomatic patients with cholelithiasis pose a more difficult management problem. Studies in adults indicate a lag time of more than a decade between initial formation of a gallstone and development of symptoms. Spontaneous resolution of cholelithiasis has been reported in infants and children. If surgery is deferred for any patient, however, parents should be counseled about signs and symptoms consistent with cholecystitis or obstruction of the common bile duct by a gallstone. In patients with chronic hemolysis or ileal disease, cholecystectomy can be carried out at the same time as another surgical procedure. Because laparoscopic surgery can safely be performed in children with sickle cell disease, elective cholecystectomy is being done more frequently at the time of gallstone diagnosis, before symptoms or complications develop. In cases associated with liver disease, severe obesity, or cystic fibrosis, the surgical risk of cholecystectomy may be substantial so that the risks and benefits of the operation need to be carefully considered.

BILIARY DYSKINESIA

Biliary dyskinesia is a motility disorder of the biliary tract that may cause acalculous biliary colic in children, often in association with nausea and fatty food intolerance. There are usually no gallstones on imaging. Sphincter of Oddi dysfunction may be a variant that can present with chronic abdominal pain and recurrent pancreatitis. The diagnosis is based on a cholecystokinin–diisopropyl iminodiacetic acid scan demonstrating a gallbladder ejection fraction of less than 35%. Reproduction of pain on cholecystokinin administration may also be seen, as well as the absence of gallbladder filling on an otherwise normal ultrasound examination. In several recent reports, laparoscopic cholecystectomy was effective in providing both short-term and long-term improvement of symptoms in most children with biliary dyskinesia.

Chapter 367

Portal Hypertension and Varices

Frederick J. Suchy

Portal hypertension, defined as an elevation of portal pressure >10-12 mm Hg, is a major cause of morbidity and mortality in children with liver disease. The normal portal venous pressure is approximately 7 mm Hg. The clinical features of the various forms of portal hypertension may be similar, but the associated complications, management, and prognosis can vary significantly and depend on whether the process is complicated by hepatic insufficiency.

ETIOLOGY

Portal hypertension can result from obstruction to portal blood flow anywhere along the course of the portal venous system. Table 367-1 outlines the various disorders associated with portal hypertension. Portal hypertension can occur as a result of prehepatic, intrahepatic, or posthepatic obstruction to the flow of portal blood.

Extrahepatic portal vein obstruction is an important cause of portal hypertension in childhood. The obstruction can occur at any level of the portal vein. Umbilical infection (**omphalitis**) with or without a history of catheterization of the umbilical vein may be causal in neonates. The infection can potentially spread from the umbilical vein to the left branch of the portal vein and eventually to the main portal venous channel. Intraabdominal infections, including acute

Table 367-1 Causes of Portal Hypertension

EXTRAHEPATIC PORTAL HYPERTENSION
Portal vein agenesis, atresia, stenosis
Portal vein thrombosis or cavernous transformation
Splenic vein thrombosis
Increased portal flow
Arteriovenous fistula
INTRAHEPATIC PORTAL HYPERTENSION
Hepatocellular disease
Acute and chronic viral hepatitis
Cirrhosis
Congenital hepatic fibrosis
Wilson disease
α_1-Antitrypsin deficiency
Glycogen storage disease type IV
Hepatotoxicity
Methotrexate
Parenteral nutrition
Biliary tract disease
Extrahepatic biliary atresia
Cystic fibrosis
Choledochal cyst
Sclerosing cholangitis
Intrahepatic bile duct paucity
Idiopathic portal hypertension
Postsinusoidal obstruction
Budd-Chiari syndrome
Venoocclusive disease

appendicitis and primary peritonitis, can be causal in older children. Portal vein thrombosis is also associated with neonatal dehydration and systemic infection. In older children, inflammatory bowel disease can be associated with a hypercoagulable state and portal venous obstruction. Thrombosis of the portal vein has also occurred in association with biliary tract infections and primary sclerosing cholangitis. **Portal vein thrombosis** is associated with hypercoagulable states, such as deficiencies of factor V Leiden, protein C, or protein S. The portal vein can be replaced by a fibrous remnant or contain an organized thrombus. Rare developmental anomalies producing extrahepatic portal hypertension include agenesis, atresia, or stenosis of the portal vein. Obstruction by a web or diaphragm can also occur. At least half of reported cases have no defined cause.

Uncommonly, presinusoidal hypertension can be caused by increased flow through the portal system as a result of a congenital or acquired arteriovenous fistula.

The intrahepatic causes of portal hypertension are numerous. Obstruction to flow can occur on the basis of a presinusoidal process, including acute and chronic hepatitis, congenital hepatic fibrosis, and schistosomiasis. Portal infiltration with malignant cells or granulomas can also contribute. An idiopathic form of portal hypertension characterized by splenomegaly, hypersplenism, and portal hypertension without occlusion of portal or splenic veins and with no obvious disease in the liver has been described. In some patients, noncirrhotic portal fibrosis has been observed.

Cirrhosis is the predominant cause of portal hypertension and is related to obstruction of blood flow through the portal vein. The numerous causes of cirrhosis include recognized disorders such as biliary atresia, autoimmune hepatitis, chronic viral hepatitis, and metabolic liver disease such as α_1-antitrypsin deficiency, Wilson disease, glycogen storage disease type IV, hereditary fructose intolerance, and cystic fibrosis.

Postsinusoidal causes of portal hypertension are also observed in childhood. The **Budd-Chiari syndrome** occurs with obstruction to hepatic veins anywhere between the efferent hepatic veins and the entry of the inferior vena cava into the right atrium. In most cases, no specific cause can be found, but thrombosis can occur from inherited and acquired hypercoagulable states (antithrombin III deficiency, protein C or S deficiency, factor V Leiden or prothrombin mutations, paroxysmal nocturnal hemoglobinemia, pregnancy, oral contraceptives) and can complicate hepatic or metastatic neoplasms, collagen vascular disease, infection, and trauma. Additional causes of the Budd-Chiari syndrome include Behçet syndrome, inflammatory bowel disease, aspergillosis, dacarbazine therapy, and inferior vena cava webs.

Sinusoidal obstruction syndrome (venoocclusive disease) is the most common cause of hepatic vein obstruction in children. In this disorder, occlusion of the centrilobular venules or sublobular hepatic veins occurs. The disorder occurs after total body irradiation with or without cytotoxic drug therapy that is commonly used before bone marrow transplantation. The disease has also occurred after ingestion of herbal remedies containing the pyrrolizidine alkaloids, which are sometimes taken as medicinal teas.

PATHOPHYSIOLOGY

The primary hemodynamic abnormality in portal hypertension is increased resistance to portal blood flow. This is the case whether the resistance to portal flow has an intrahepatic cause such as cirrhosis or is due to portal vein obstruction. Portosystemic shunting should decompress the portal system and thus significantly lower portal pressures. Despite the development of significant collaterals deviating portal blood into systemic veins, portal hypertension is maintained by an overall increase in portal venous flow and thus maintenance of portal hypertension. A hyperdynamic circulation is achieved by tachycardia, an increase in cardiac output, and decreased systemic vascular resistance. Splanchnic dilation also occurs. Overall, the increase in portal flow likely contributes to an increase in variceal transmural pressure. The increase in portal blood flow is related to the contribution of hepatic and collateral flow; the actual portal blood flow reaching the liver is reduced. It is also likely that hepatocellular dysfunction and portosystemic shunting lead to the generation of various humoral factors that cause vasodilation and an increase in plasma volume.

Many complications of the portal hypertension can be accounted for by the development of a remarkable collateral circulation. Collateral vessels can form prominently in areas in which absorptive epithelium joins stratified epithelium, particularly in the esophagus or anorectal region. The superficial submucosal collaterals, especially those in the esophagus and stomach and, to a lesser extent, those in the duodenum, colon, or rectum, are prone to rupture and bleeding under increased pressure. In portal hypertension, the vascularity of the stomach is also abnormal and demonstrates prominent submucosal arteriovenous communications between the muscularis mucosa and dilated precapillaries and veins. The resulting lesion, a vascular ectasia, has been called **congestive gastropathy** and contributes to a significant risk of bleeding from the stomach.

CLINICAL MANIFESTATIONS

Bleeding from esophageal varices is the most common presentation. Less commonly, patients bleed from varices around a stoma or from anorectal varices. In patients with underlying hepatic disease, physical examination might show jaundice and stigmata of cirrhosis such as palmar erythema and vascular telangiectasias. Growth retardation can occur in patients with cirrhosis and, to a lesser extent, in children with isolated extrahepatic portal vein obstruction. Ascites may be present in patients with intrahepatic causes of portal hypertension and can transiently occur with portal vein obstruction. Dilated cutaneous collateral vessels carrying blood from the portal to systemic circulation may be apparent in the periumbilical region. In the absence of clinical or biochemical features of liver disease and with a liver of normal size, portal vein obstruction is most likely. Well-compensated cirrhosis cannot be completely ruled out under these conditions. Cholestasis and liver dysfunction with elevated serum bilirubin and aminotransferases occur uncommonly in portal vein obstruction as a result of external compression of bile ducts by cavernous transformation of the portal vein. This complication is called **portal hypertensive biliopathy**.

An enlarged, hard liver with minimal disturbance of hepatic function suggests the possibility of congenital hepatic fibrosis.

Hemorrhage, particularly in children with portal vein obstruction, can be precipitated by minor febrile, intercurrent illness. The mechanism is often unclear; aspirin or other nonsteroidal antiinflammatory drugs may be a contributing factor by damaging the integrity of a congested gastric mucosa or interfering with platelet function. Coughing during a respiratory illness can also increase intravariceal pressure. The bleeding may become apparent with hematemesis or with melena. Gastrointestinal hemorrhage can also originate from portal hypertensive gastropathy or from gastric, duodenal, peristomal, or rectal varices.

Splenomegaly, sometimes with hypersplenism, is the next most common presenting feature in portal vein obstruction and may be discovered first on routine physical examination. Because more than half of patients in many series with portal vein obstruction do not experience bleeding until after age 6 yr, the diagnosis should be suggested in a child without hepatocellular disease who had a complicated neonatal course and in whom asymptomatic splenomegaly later developed. Long-term follow-up of patients with portal vein obstruction has revealed a variety of complications including variceal hemorrhage, hypersplenism, biliary obstruction, growth and development retardation, and neuropsychiatric dysfunction.

Children with portal hypertension, regardless of the underlying cause, may have recurrent bouts of life-threatening hemorrhage. In patients with portal vein obstruction and normal hepatic function, the bleeding usually stops spontaneously. In patients with intrahepatic disease, the combination of portal hypertension and poor liver synthetic ability (coagulopathy) can make bleeding much more difficult to control. Moreover, esophageal hemorrhage and cirrhosis can have injurious effects on the liver, further impairing hepatic function and sometimes precipitating jaundice, ascites, and encephalopathy. Blood in the intestinal lumen can promote bacterial translocation, leading to peritonitis. Another serious complication is the hepatopulmonary syndrome, which develops in ≥10% of patients with portal hypertension. It is defined as an arterial oxygenation defect induced by intrapulmonary microvascular dilation, resulting from release of a number of endogenous vasoactive molecules, including endothelin-1 and nitric oxide into the venous circulation.

DIAGNOSIS

In patients with established chronic liver disease or in those in whom portal vein obstruction is suspected, an experienced ultrasonographer should be able to demonstrate the patency of the portal vein, and Doppler flow ultrasonography can demonstrate the direction of flow within the portal system. The pattern of flow correlates with the severity of cirrhosis and encephalopathy. Reversal of portal vein blood flow (hepatofugal flow) is more likely to be associated with variceal bleeding. Ultrasonography is also effective in detecting the presence of esophageal varices. Another important feature of extrahepatic portal vein obstruction is cavernous transformation of the portal vein, in which an extensive complex of small collateral vessels form in the paracholedochal and epicholedochal venous system to bypass the obstruction. Other imaging techniques also contribute to further definition of the portal vein anatomy but are required less often; contrast-enhanced CT and magnetic resonance angiography provide information similar to ultrasonography. Selective arteriography of the celiac axis, superior mesenteric artery, and splenic vein may be useful in precise mapping of the extrahepatic vascular anatomy. This is not required to establish a diagnosis but can prove valuable in planning surgical decompression of portal hypertension. The platelet count, spleen length measured by ultrasonography, and serum albumin are the best noninvasive predictors of portal hypertension in children.

In a patient with hypoxia (**hepatopulmonary syndrome**), intrapulmonary microvascular dilation is demonstrated with contrast-enhanced echocardiography that shows delayed appearance in the left heart of microbubbles from a saline bolus injected into a peripheral vein.

Endoscopy is the most reliable method for detecting esophageal varices and for identifying the source of gastrointestinal bleeding. Although bleeding from esophageal or gastric varices is most common in children with portal hypertension, up to one third of patients, particularly those with cirrhosis, have bleeding from some other source such as portal hypertensive gastropathy or gastric or duodenal ulcerations. There is a strong correlation between variceal size as assessed endoscopically and the probability of hemorrhage. Red spots apparent over varices at the time of endoscopy are a strong predictor of imminent hemorrhage.

TREATMENT

The therapy of portal hypertension can be divided into emergency treatment of potentially life-threatening hemorrhage and prophylaxis directed at prevention of initial or subsequent bleeding. It must be emphasized that the use of many therapies is based on experience in adults with portal hypertension. There is a lack of rigorous studies on the ability of endoscopy screening, endoscopic treatment of varices, and use of nonselective β-blockers to alter the outcome of portal hypertension in children.

Treatment of patients with variceal hemorrhage must focus on fluid resuscitation, initially in the form of crystalloid infusion, followed by the replacement of red blood cells. Correction of coagulopathy by administration of vitamin K and/or infusion of platelets or fresh-frozen plasma may be required. A nasogastric tube should be placed to document the presence of blood within the stomach and to monitor for ongoing bleeding. An H_2-receptor blocker or proton pump inhibitor should be given intravenously to reduce the risk of bleeding from gastric erosions. In most patients, particularly those with extrahepatic portal hypertension and with normal hepatic synthetic function, bleeding usually stops spontaneously. Care should be taken in fluid resuscitation of children after bleeding to avoid producing an excessively high venous pressure and increasing risk for further bleeding.

Pharmacologic therapy to decrease portal pressure may be considered in patients with continued bleeding. Vasopressin or one of its analogs is commonly used and is thought to act by increasing splanchnic vascular tone and thus decreasing portal blood flow. Vasopressin is administered initially with a bolus of 0.33 units/kg over 20 min, followed by a continued infusion of the same dose on an hourly basis or a continuous infusion of 0.2 units/1.73 m^2/min. The drug has a half-life of approximately 30 min. Its use may be limited by the side effects of vasoconstriction, which can impair cardiac function and perfusion to the heart, bowel, and kidneys and can also, as a result, exacerbate fluid retention. Nitroglycerin, usually given as a portion of a skin patch, has also been used to decrease portal pressure and, when used in conjunction with vasopressin, can ameliorate some of its untoward effects. The somatostatin analog octreotide is more commonly used, and it decreases splanchnic blood flow with fewer side effects. It may be administered by continuous intravenous infusion of 1.0-5.0 μg/kg/hr. However, the use of octreotide in adults with variceal hemorrhage has not been associated with a reduction in rates of rebleeding or mortality. Its use and efficacy in children have not been rigorously evaluated.

After an episode of variceal hemorrhage or in patients in whom bleeding cannot be controlled, endoscopic sclerosis or elastic band ligation of esophageal varices are important options. In endoscopic sclerosis, sclerosants are injected either intravariceally or paravariceally until bleeding has stopped. Although bleeding can be controlled acutely in most cases, further sessions of sclerotherapy are required to achieve temporary obliteration of the varices. Treatments may be associated with further bleeding, bacteremia, esophageal ulceration, and stricture formation. Most centers do not perform endoscopic sclerotherapy of varices prophylactically but use the procedure as a bridge to the time of liver transplantation or a surgical shunting procedure. Endoscopic elastic band ligation of varices has been shown in adult and pediatric studies to be more effective and associated with fewer complications than is sclerotherapy.

In patients who continue to bleed despite pharmacologic and endoscopic methods to control hemorrhage, a Sengstaken-Blakemore tube may be placed to stop hemorrhage by mechanically compressing esophageal and gastric varices. The device is rarely used now, but it

may be the only option to control life-threatening hemorrhage. It carries a significant rate of complications and a high rate of bleeding when the device is removed, and it poses a particularly high risk for pulmonary aspiration. The tube is not well tolerated in children without significant sedation.

Various surgical procedures have been devised to divert portal blood flow and to decrease portal pressure. A portacaval shunt diverts nearly all of the portal blood flow into the subhepatic inferior right vena cava. Although portal pressure is significantly reduced, because of the significant diversion of blood from the liver, patients with parenchymal liver disease have a marked risk for hepatic encephalopathy. Even mild hepatic encephalopathy can impair cognitive function, including school performance. More selective shunting procedures, such as mesocaval or distal splenorenal shunt, can effectively decompress the portal system while allowing a greater amount of portal blood flow to the liver. The small size of the vessels makes these operations technically challenging in infants and small children, and there is a significant risk of failure as a result of shunt thrombosis. A shunt may be good option in a child with relatively well-preserved liver function, as sometimes occurs in patients with biliary atresia, congenital hepatic fibrosis, or cystic fibrosis. Portal vein thrombosis has been managed with the Rex shunt (superior mesenteric vein to left portal vein bypass), which restores physiologic portal blood flow and inflow of hepatotrophic factors. Growth and cognitive function improve after this procedure.

A transjugular intrahepatic portosystemic shunt, in which a stent is placed by an interventional radiologist between the right hepatic vein and the right or left branch of the portal vein, can aid in the management of portal hypertension in children, especially in those needing temporary relief before liver transplantation. The transjugular intrahepatic portosystemic shunt procedure can precipitate hepatic encephalopathy and is prone to thrombosis.

Orthotopic liver transplantation represents a much better therapy for portal hypertension resulting from intrahepatic disease and cirrhosis. A prior portosystemic shunting operation does not preclude a successful liver transplantation but makes the operation technically more difficult.

Long-term treatment with nonspecific β-blockers, such as propranolol, has been used extensively in adults with portal hypertension. These agents might act by lowering cardiac output and portal perfusion. Evidence in adult patients shows that β-blockers can reduce the incidence of variceal hemorrhage and improve long-term survival. A therapeutic effect is thought to result when the pulse rate is reduced by ≥25%. There is limited published experience with the use of this therapy in children.

PROGNOSIS

Portal hypertension secondary to intrahepatic disease has a poor prognosis. Portal hypertension is usually progressive in these patients and is often associated with deteriorating liver function. Efforts should be directed toward prompt treatment of acute bleeding and prevention of recurrent hemorrhage with available methods. Patients with progressive liver disease and significant esophageal varices ultimately require orthotopic liver transplantation. Liver transplantation is the only effective therapy for hepatopulmonary syndrome and should also be considered for patients with portal hypertension secondary to hepatic vein obstruction or resulting from severe venoocclusive disease.

In patients with portal vein obstruction, episodes of bleeding can become less frequent and severe with age as a collateral circulation develops, >50% experience bleeding during adolescence. Neurocognitive defects diagnosed by careful psychologic testing indicate portosystemic encephalopathy caused by naturally occurring portosystemic shunts. Progressive liver disease can occur later as a consequence of bile duct compression from dilated collateral venous channels (portal biliopathy). These complications can be treated or prevented by the Rex shunt.

Chapter 368

Liver Transplantation

Jorge D. Reyes and Evelyn Hsu

Refinements in the management of hepatic failure, organ procurement and implantation techniques, organ preservation, perioperative care, and the development of effective immunosuppressive management (cyclosporine in 1978 and tacrolimus in 1989) survival rates for liver transplantation is now >90%. Complications inherent in the toxicity/infection profile of immunosuppressive drug therapy have occurred and enhancements in our understanding of the relationship between recipient and host immune systems have resulted in the development of tailored immunotherapy. In addition, the search for "tolerance" enhancing protocols, which could lead to transplantation without the need for long-term immunosuppression. The creation of a national system for matching these donor organs with waiting recipients (the Organ Procurement and Transplantation Network and the United Network for Organ Sharing [UNOS]) provides equitable sharing of this scarce organ resource to the neediest patients with the adoption of the Pediatric End-Stage Liver Disease and Medical End-Stage Liver Disease (for adolescents) scoring systems.

INDICATIONS

The diseases for which liver transplantation is indicated can be categorized into the following groups:

- Obstructive biliary tract disease: biliary atresia, sclerosing cholangitis, traumatic or postsurgical injury
- Metabolic disorders: α_1-antitrypsin deficiency, tyrosinemia type I, glycogen storage disease type IV, Wilson disease, neonatal hemochromatosis, Crigler-Najjar type I, familial hypercholesterolemia, primary oxalosis, organic academia, urea cycle defects
- Acute hepatitis: fulminant hepatic failure, viral, toxin, or drug induced
- Chronic hepatitis with cirrhosis: hepatitis B or C, autoimmune
- Intrahepatic cholestasis: idiopathic neonatal hepatitis, Alagille syndrome, progressive familial intrahepatic cholestasis
- Miscellaneous: cryptogenic cirrhosis, congenital hepatic fibrosis, Caroli disease, cystic fibrosis, polycystic kidney and liver disease, cirrhosis induced by total parenteral nutrition
- Primary liver tumors: benign tumors (hamartomas, hemangioendothelioma), unresectable hepatoblastoma, and hepatocellular carcinoma
- Emerging indications: graft-versus-host-disease (a complication of bone marrow transplantation), hemophilia, and portosystemic shunts

Biliary atresia is the most common indication for liver transplantation in children, followed by metabolic and inborn disorders, autoimmune and familial cholestatic disorders, and acute hepatic necrosis.

Biliary atresia may present with 2 clinical patterns: an acquired form for which there may be nonrandom clustering of potential etiologies (80% of cases), and a syndromic/embryonic form that includes other anomalies, such as polysplenia or asplenia, preduodenal portal vein, intestinal malrotation, situs anomalies, and absence of the retrohepatic vena cava. Hepatoportoenterostomy may benefit survival if performed within the 1st 30 days of life, however, some patients with successful drainage later develop cirrhosis with portal hypertension (variceal bleeding and ascites). Children with biliary atresia (or any other obstructive biliary disorder) who do not achieve successful drainage require liver transplantation within the 1st yr of life.

Inborn errors of metabolism result from a single enzyme deficiency that results in alteration of synthesis, breakdown, transport, or function of carbohydrate, fat, or protein. They can be grouped into those diseases which cause structural damage and cirrhosis, and potentially end-stage liver disease, as well as liver cancer (i.e., α_1-antitrypsin deficiency, Wilson disease, cystic fibrosis, progressive familial intrahepatic cholestasis), and those inborn errors that manifest principally by their hepatic enzyme deficiency with no hepatocellular injury; complications occur in "satellite" systems such as the brain (hyperammonemic conditions), the kidney (hyperoxaluria type 1), or heart (familial hypercholesterolemia). Some metabolic disorders place patients at risk for decompensation throughout their entire lives, and others (e.g., Crigler-Najjar) manifest principally after adolescence. Liver transplantation replaces the enzyme deficiency; the value and risk benefit of doing so in the absence of cirrhosis has prompted the pursuit of gene therapy and hepatocyte transplantation as possible alternatives, but their therapeutic benefit is yet to be determined.

Although many patients with **fulminant hepatic failure** will survive without transplant, it accounts for approximately 13% of pediatric liver transplantation and has required the most intense concentration of multimodal management/support, and organ graft options yet devised. It is a diagnosis without clear etiology in more than 50% of cases, and posttransplantation survival varies but is generally poor because of multifactorial issues related to comorbidities and listing/transplantation graft option availability.

Primary hepatic malignancies in children are rare (<2% of all pediatric malignancies), and account for a little less than 10% of transplants. Hepatoblastoma accounts for the majority of cases (75% of primary liver tumors in childhood) and is usually of an advanced stage, yet adjuvant chemotherapy and total hepatectomy with transplantation provide cure and long-term survival for the majority of patients thus treated. Survival of >85% has been reported by the International Society of Pediatric Oncology and several American centers.

Some diseases do not produce life-threatening complications, yet their impact on growth, development, and quality of life can be so devastating that liver transplantation is a valid therapy and cure. The distribution of liver grafts does follow guidelines based on severity of liver disease as reflected in the Pediatric End-Stage Liver Disease scoring system developed by UNOS, which takes into calculation the measurable values of bilirubin, creatinine, and international normalization ratio.

Contraindications to liver transplantation include uncontrolled infection of extrahepatic origin, uncontrolled extrahepatic malignancies, and severely disabling and uncorrectable disease in other organ systems, principally the heart and lungs. Although combined liver and heart or lung transplantation has been performed in adults and children, such cases require special consideration and centers dedicated to the complexities of posttransplantation management. Also, disabling neurologic disease can preclude liver transplantation if the outcome will not allow the child to develop some measure of independence and quality of life.

TECHNICAL INNOVATIONS

There are no limitations on age or weight for liver transplantation, a consequence to improved posttransplantation outcomes as a result of improvements in perioperative management (recipient selection, care, and timing of transplantation as well as intra- and posttransplantation care), and to the development and successful transplantation of segmental liver grafts.

To enhance the availability of liver grafts to children and optimize the timing of transplantation, the use of reduced-size or segmental grafts (a right or left lobe of liver, or the left lateral segment of the left lobe) were developed; this advancement allows the selection of a liver from a larger donor for implantation into a child, thus correcting the size mismatch. Because liver reduction inherently removes a potential graft for an adult recipient, techniques were developed for the use of segments from living donors (using usually the left lateral segment for small pediatric recipients), and then split-liver grafts from deceased donors where the left lateral segment is transplanted into a child and the leftover segment of right lobe and medial segment of left lobe (essentially a right trisegment graft) are transplanted into an adult. Reduction of a liver graft is performed ex vivo; split-liver grafts can be accomplished either ex vivo or in situ (in the hemodynamically stable brain-dead donor). Donors suitable for aforementioned graft variants should ideally be young (younger than 45 yr of age), healthy, and nonobese; however, variations are guided by the severity of illness and urgency for transplantation of the recipient.

The implantation of a liver (either whole organ or segment) involves removal of the native liver and encompasses 4 anastomoses: the suprahepatic vena cava, the portal vein, the hepatic artery, and the bile duct. Modifications of the procedure generally involve retaining (or not) of the retrohepatic vena cava, the performance (or not) of a temporary portocaval shunt to decompress the splanchnic venous system during the anhepatic phase, and the use of vascular homografts of donor iliac vein or artery to replace the native inflow (guided by the presence of recipient anomalies or thrombosis of native vessels). The donor bile duct may be connected to a loop of recipient intestine (Roux-en-Y limb) or the native bile duct.

UNOS reported outcomes analyzing graft types and outcomes have shown improved graft survival in children younger than 3 yr of age for live donor grafts when compared to deceased donor whole, split, and reduced grafts. After the 1st yr, however, patient and allograft survivals were similar regardless of whether the graft was a whole liver, deceased donor segment, or living donor.

IMMUNOSUPPRESSION

The goal of effective clinical immunosuppression after solid-organ transplantation is to inhibit antigen-induced T-lymphocyte activation and cytokine production, interrupt allo–major histocompatibility complex recognition, or block effector responses. To prevent overly weakening the host response to infection, these effects should be accomplished while preserving immunocompetence. A major emphasis is the prevention of acute and chronic rejection and the ability to reverse refractory acute rejection. These efforts have been, for the most part, successful; the current challenge is long-term survival and quality of life, inherently involving strategies to minimize the long-term toxicity of immunosuppressive drug therapy, which can include renal failure, cardiovascular complications, and infections. Studies have led to a better understanding of lymphocyte subsets and function, the discovery that rejection could be reversed with steroids or antilymphocyte globulin, and then the realization that long-lasting donor-specific unresponsiveness could be achieved with less drug therapy, while preserving immunocompetence.

Immediately peri- or posttransplantation therapy may involve antilymphocyte antibody induction with depleting antibodies (monoclonal or polyclonal) such as antithymocyte globulin antibody, or the use of a chimeric mouse–human antibody that blocks the interleukin-2 receptor of the T cell, thus preventing activation and replication of antigen-selected T cells. Corticosteroids act through the suppression of antibody production and cytokine synthesis (interleukin-2, and interferon-γ), decreasing proliferation of T cells (helper, suppressor, and cytotoxic), B cells, and neutrophils. Maintenance immunosuppression is achieved through the use of calcineurin phosphatase inhibitor activity using drugs such as cyclosporine or tacrolimus; these drugs interfere with the production and release of interleukin-2 which plays a critical role in the cytotoxic T-cell response, thus inhibiting T-cell–mediated acute cellular rejection. Tacrolimus has shown to be a more powerful drug, however, the ability to progress or initiate maintenance immunosuppression in the absence of corticosteroids is of particular benefit in the children. Other drugs, such as azathioprine or mycophenolate mofetil, which inhibit the synthesis of purine nucleosides and thus the proliferation of T and B lymphocytes and antibody formation, may be added to enhance the antirejection profile, allow for decrease in the calcineurin dosage, or manage chronic rejection. Rapamycin, a macrolide which binds its' molecular target of mammalian target of rapamycin receptor, decreases

interleukin-2 production, and thus T- and B-cell activation and proliferation.

COMPLICATIONS

Posttransplantation complications can be related to the pretransplantation condition of the recipient and the donor match and type, immunologic responses to the graft and the need for enhanced immunosuppressive drug therapy, and toxicity effects of these drugs or infections from over-immunosuppression. They can occur at varying specific frequencies over a fairly well-defined time course (early, late, remote).

The most predictable complications involve those inherent to the transplantation operation and include primary nonfunction of the graft (rare in pediatric recipients given the selection criteria of potential donors); hepatic artery thrombosis is the most frequent and early vascular complication, occurring in 5-10% of recipients and can have devastating consequences on the graft (acute necrosis and gangrene, and biliary leaks/stricture/bilomas), which may require urgent retransplantation; portal vein or hepatic vein strictures/occlusions are rare and generally occur later posttransplantation. Biliary strictures are the most frequent surgical complication (10-30%) after liver transplantation and should be included in the differential diagnosis of any posttransplantation liver allograft dysfunction. Management of these complication varies and may include interventional radiologic procedures, reoperation, or retransplantation.

Rejection usually occurs after the 1st 2 wk after transplantation, with the highest incidence (30-60%) within the 1st 90 days. Diagnosis is suspected based on abnormal liver function studies, and rarely are there systemic signs such as fever, abdominal pain, new-onset ascites or hydrothorax; the diagnosis requires biopsy confirmation; treatment algorithms include high doses of corticosteroids and antilymphocyte antibodies. Chronic rejection is less frequent (5-10%) and is characterized by progressive damage and loss of bile ductules with consequent cholestasis; treatment involves long-term enhancement of maintenance immunosuppression with corticosteroids and other agents.

The need to treat rejection can place the patient at a higher risk of drug toxicity or infection. The most common transplantation-related infections are cytomegalovirus and Epstein-Barr virus infections, for which there are well-developed algorithms of prophylaxis. Epstein-Barr virus-induced **posttransplant lymphoproliferative disease** represents a unique complication of over-immunosuppression and infection occurring in approximately 10% of patients, and that has been managed by withdrawal of immunosuppression and antiviral therapy; some patients require chemotherapy.

OUTCOMES

The clinical, surgical, and immunosuppressive drug therapy advances since the 1990s have dramatically improved survival of liver transplantation in children. The SPLIT registry data (1092 patients in North America transplanted since 1995) demonstrate 1-yr patient and graft survival of 86.3% and 80.2%, respectively. UNOS data reveal a 1 yr patient and graft survival for biliary atresia of 95% and 87% respectively. Longer-term survival is inherently dependent on adequacy of long term immunosuppression management, adherence to care protocols, and prevention of infection/toxicities/chronic rejection.

With longer survival times, the issues of growth, quality of life, and patient loss with a functioning graft have come to the forefront. The goals have been reset to seek the induction protocols and strategies that can foster minimization of drug therapy and even a drug-free state, the induction of tolerance.

Section 7

Peritoneum

Chapter 369

Malformations

Melissa Kennedy and Chris A. Liacouras

Congenital peritoneal bands represent anatomically unabsorbed portions of omentum and mesentery and most commonly occur in the regions of the duodenum, duodenojejunal flexure, ileocecal junction, and ascending colon. Although usually benign, they may be responsible for intestinal obstruction or midgut volvulus and resulting intestinal necrosis. Intraabdominal herniations infrequently occur through ring-like formations produced by anomalous peritoneal bands. Numerous other anomalies can occur in the course of the development of the peritoneum but are rarely of clinical importance. Absence of the omentum or its duplication occurs rarely. Omental cysts arise in obstructed lymphatic channels within the omentum. They may be congenital or can result from trauma and are usually asymptomatic. Abdominal pain or partial small bowel obstruction can result from compression or torsion of the small bowel from traction on the omentum.

Chapter **370**

Ascites

Melissa Kennedy and Chris A. Liacouras

Ascites is the pathologic accumulation of fluid within the peritoneal cavity. Multiple causes of ascites have been described (Table 370-1). In children, hepatic and renal disease are the most common causes, but ascites can also be caused by cardiac disease, trauma, infection, or neoplasia.

The clinical hallmark of ascites is abdominal distention. Early satiety and dyspnea can occur with a moderate amount of ascites. Considerable intraperitoneal fluid can accumulate before ascites is detectable by the classic physical signs: bulging flanks, dullness to percussion, shifting dullness, a fluid wave, and the "puddle sign" (percussion of a supine person's abdomen over the umbilicus becomes dull as the patient is moved to a prone position and ascitic fluid puddles in dependent regions). Umbilical herniation can be associated with tense ascites. Ultrasound examination is useful for detecting small amounts of ascites.

Abdominal paracentesis can provide symptomatic relief and may be diagnostic of the cause of the ascites. Determining the serum-ascites albumin gradient can help to determine the cause of ascites. A gradient greater than 1.1 g/dL (high-gradient ascites) is consistent with ascites caused by portal hypertension, whereas a gradient <1.1 g/dL (low-gradient ascites) indicates ascites of nonportal-hypertensive etiology.

The course, prognosis, and treatment of ascites depend entirely on the cause. For most patients, treatment consists of dietary sodium restriction and diuretic therapy with spironolactone, with the addition of furosemide in more severe cases. Supplemental albumin can also aid in ascitic fluid mobilization. Refractory cases may require large volume paracentesis or transjugular intrahepatic portosystemic shunting.

Table 370-1	Causes of Ascites
HEPATIC Cirrhosis Congenital hepatic fibrosis Portal vein obstruction Fulminant hepatic failure Budd-Chiari syndrome Lysosomal storage disease

Patients with any type of ascites are at increased risk for spontaneous bacterial peritonitis.

Bibliography is available at Expert Consult.

370.1 Chylous Ascites

Jessica W. Wen and Chris A. Liacouras

Chylous ascites refers to peritoneal fluid that contains lymphatic drainage with a characteristic milky appearance that is rich in triglycerides. Chylous ascites can result from congenital anomaly, injury, or obstruction of the intra-abdominal portion of the thoracic duct. Although uncommon, it can occur at any age. In the pediatric population, the most common cause is lymphatic malformation. Other causes include surgical injury to the lymphatics, trauma, cirrhosis, peritoneal bands, generalized lymphangiomatosis, chronic inflammatory processes of the bowel, and mycobacterial infection. Malignancy is a fairly common cause in the adult population but uncommon in pediatrics. Congenital anomalies of the lymphatic system can be associated with Turner, Noonan, yellow nail, and Klippel-Trenaunay-Weber syndromes.

The most common presentation is painless abdominal distention, and it may be accompanied by poor weight gain and loose stools. Peripheral edema is common. Massive chylous ascites can result in scrotal edema, inguinal and umbilical herniation, and respiratory difficulties.

Diagnosis of chylous ascites depends on the demonstration of milky ascitic fluid obtained via paracentesis after a fat-containing feeding. Ascites fluid analysis reveals high protein content, elevated triglycerides, and lymphocytosis. If the patient has had nothing by mouth, the fluid may appear serous. Hypoalbuminemia, hypogammaglobulinemia, and lymphopenia are common in these patients.

Treatment includes a high-protein, low-fat diet supplemented with medium-chain triglycerides that are absorbed directly into the portal circulation and decrease lymph production. Parenteral alimentation may be necessary if nutrition remains impaired on oral feedings this may also significantly decrease lymph flow and facilitate sealing at the point of lymph leakage. Octreotide, a somatostatin analog, has been used by subcutaneous route in chylous ascites. The mechanism is not clearly understood; however, it decreases intestinal blood flow leading to decreased portal pressure and it also inhibits lymphatic secretion through somatostatin receptors in the intestinal wall. Paracentesis should be repeated only if abdominal distention causes respiratory distress. Laparotomy may be indicated to search for the site of the leakage if a trial of dietary management has been unsuccessful and a lymphangiogram demonstrates site of leakage.

Chapter 371

Peritonitis

Jessica W. Wen and Chris A. Liacouras

Inflammation of the peritoneal lining of the abdominal cavity can result from infectious, autoimmune, neoplastic, and chemical processes. Infectious peritonitis is usually defined as primary (spontaneous) or secondary. In primary peritonitis, the source of infection originates outside the abdomen and seeds the peritoneal cavity via hematogenous, lymphatic, or transmural spread. Secondary peritonitis arises from the abdominal cavity itself through extension from or rupture of an intraabdominal viscus or an abscess within an organ. Tertiary peritonitis refers to recurrent diffuse or localized disease and is associated with poorer outcomes than secondary peritonitis.

Clinically, patients have abdominal pain, abdominal tenderness, and rigidity on exam. Peritonitis can result from rupture of a hollow viscus, such as the appendix or a Meckel diverticulum; disruption of the peritoneum from trauma or peritoneal dialysis catheter; chemical peritonitis from other bodily fluid, including bile and urine; and infection. Meconium peritonitis is described in Chapters 102.1 and 330. Peritonitis is considered a surgical emergency and requires exploration and lavage of the abdomen except in spontaneous bacterial peritonitis.

Bibliography is available at Expert Consult.

371.1 Acute Primary Peritonitis

Jessica W. Wen and Chris A. Liacouras

ETIOLOGY AND EPIDEMIOLOGY

Primary peritonitis usually refers to bacterial infection of the peritoneal cavity without a demonstrable intraabdominal source. Most cases occur in children with ascites resulting from cirrhosis and nephrotic syndrome. Infection can result from translocation of gut bacteria as

Bibliography

Singh S, Khardori NM: Intra-abdominal and pelvic emergencies, *Med Clin North Am* 96:1171–1191, 2012.

well as immune dysfunction. Rarely, primary peritonitis occurs in previously healthy children. Pneumococci (most common), group A streptococci, enterococci, staphylococci, and Gram-negative enteric bacteria, especially *Escherichia coli* and *Klebsiella pneumoniae,* are most commonly found. *Mycobacterium tuberculosis, Neisseria meningitidis,* and *Mycobacterium bovis* are rare causes.

CLINICAL MANIFESTATIONS

Onset may be insidious or rapid and is characterized by fever, abdominal pain and a toxic appearance. Vomiting and diarrhea may be present. Hypotension and tachycardia are common along with shallow, rapid respirations because of discomfort associated with breathing. Abdominal palpation might demonstrate rebound tenderness and rigidity. Bowel sounds are hypoactive or absent. However, signs and symptoms may be subtle at times and increase vigilance is needed in cirrhotic patients who have ascites and present with unexplained leukocytosis, azotemia, or metabolic acidosis.

DIAGNOSIS AND TREATMENT

Peripheral leukocytosis with a marked predominance of polymorphonuclear cells is common, although the white blood cell (WBC) count can be affected by preexisting hypersplenism in patients with cirrhosis. Patients with nephrotic syndrome generally have proteinuria, and low serum albumin in these patients is associated with increased risk of peritonitis. X-ray examination of the abdomen reveals dilation of the large and small intestines, with increased separation of loops secondary to bowel wall thickening. Distinguishing primary peritonitis from appendicitis may be impossible in patients without a history of nephrotic syndrome or cirrhosis; accordingly, the diagnosis of primary peritonitis is made by CT scan, laparoscopy, or laparotomy. In a child with known renal or hepatic disease and ascites, the presence of peritoneal signs should prompt diagnostic paracentesis. Infected fluid usually reveals a WBC count of ≥250 cells/mm^3, with >50% polymorphonuclear cells.

Primary peritonitis is usually monomicrobial. The presence of mixed bacterial flora on ascitic fluid examination or free air on abdominal roentgenogram in children with presumed peritonitis mandates laparotomy to localize a perforation as a likely intraabdominal source of the infection. Inoculation of ascitic fluid obtained at paracentesis directly into blood culture bottles increases the yield of positive cultures. Parenteral antibiotic therapy with broad spectrum coverage, such as cefotaxime, should be started promptly, with subsequent changes dependent on sensitivity testing (vancomycin for resistant pneumococci). Therapy should be continued for 10-14 days.

Culture-negative neutrocytic ascites is a variant of primary peritonitis with a ascetic fluid WBC count of >500 cells/mm^3, a negative culture, no intraabdominal source of infection, and no prior treatment with antibiotics. It should be treated in a similar manner as primary peritonitis.

Bibliography is available at Expert Consult.

371.2 Acute Secondary Peritonitis

Jessica W. Wen and Chris A. Liacouras

Acute secondary peritonitis most often results from entry of enteric bacteria into the peritoneal cavity through a necrotic defect in the wall of the intestines or other viscus as a result of obstruction or infarction or after rupture of an intraabdominal visceral abscess. It most commonly follows perforation of the appendix. Other causes include incarcerated hernias, rupture of a Meckel diverticulum, midgut volvulus, intussusception, hemolytic uremic syndrome, peptic ulceration, inflammatory bowel disease, necrotizing cholecystitis, necrotizing enterocolitis, typhlitis, and traumatic perforation.

Peritonitis in the neonatal period most often occurs as a complication of necrotizing enterocolitis but may be associated with meconium ileus or spontaneous (or indomethacin-induced) rupture of the stomach or intestines. In postpubertal girls, bacteria from the genital tract *(Neisseria gonorrhoeae, Chlamydia trachomatis)* can gain access to the peritoneal cavity via the fallopian tubes, causing secondary peritonitis. The presence of a foreign body, such as a ventriculoperitoneal catheter or peritoneal dialysis catheter, can predispose to peritonitis, with skin microorganisms, such as *Staphylococcus epidermidis, Staphylococcus aureus,* and *Candida albicans,* contaminating the shunt. Secondary peritonitis results from direct toxic effects of bacteria as well as local and systemic release of inflammatory mediators in response to organisms and their products (lipopolysaccharide endotoxin). The development of sepsis depends on various host and disease factors, as well as promptness of antimicrobial and surgical intervention.

CLINICAL MANIFESTATIONS

Similar to primary peritonitis, characteristic symptoms include fever, diffuse abdominal pain, nausea, and vomiting. Physical findings of peritoneal inflammation include rebound tenderness, abdominal wall rigidity, a paucity of body motion (lying still), and decreased or absent bowel sounds from paralytic ileus. Massive exudation of fluid into the peritoneal cavity, along with the systemic release of vasodilative substances, can lead to the rapid development of shock. A toxic appearance, irritability, and restlessness are common. Basilar atelectasis as well as intrapulmonary shunting can develop, with progression to acute respiratory distress syndrome.

Laboratory studies reveal a peripheral WBC count >12,000 cells/mm^3, with a marked predominance of polymorphonuclear forms. X-rays of the abdomen can reveal free air in the peritoneal cavity, evidence of ileus or obstruction, peritoneal fluid, and obliteration of the psoas shadow. Other peritoneal fluid findings suggestive of secondary peritonitis include elevated total protein (>1 g/dL), low glucose (<50 mg/dL).

TREATMENT

Aggressive fluid resuscitation and support of cardiovascular function should begin immediately. Stabilization of the patient before surgical intervention is mandatory. Antibiotic therapy must provide coverage for organisms that predominate at the site of presumed origin of the infection. In contrast to primary peritonitis, secondary peritonitis is typically polymicrobial. For perforation of the lower gastrointestinal tract, a regimen of ampicillin, gentamicin, and clindamycin or metronidazole will adequately address infection by *E. coli, Klebsiella,* and *Bacteroides* spp. and enterococci. Alternative therapy could include ticarcillin-clavulanic acid and an aminoglycoside or piperacillin/tazobactam. Surgery to repair a perforated viscus should proceed after the patient is stabilized and antibiotic therapy is initiated. Intraoperative peritoneal fluid cultures will indicate whether a change in the antibiotic regimen is warranted. Empirical treatment for peritoneal dialysis catheter–related peritonitis may include intraperitoneal cefepime or cefazolin plus ceftazidime. Serious infection from peritoneal dialysis catheters can generally be prevented with good catheter hygiene and prompt removal and replacement with signs of progressive infection.

Bibliography is available at Expert Consult.

371.3 Acute Secondary Localized Peritonitis (Peritoneal Abscess)

Jessica W. Wen and Chris A. Liacouras

ETIOLOGY

Intraabdominal abscesses occur less commonly in children and infants than in adults, but can develop in visceral intraabdominal organs (hepatic, splenic, renal, pancreatic, tuboovarian abscesses) or in the interintestinal, periappendiceal, subdiaphragmatic, subhepatic, pelvic, or retroperitoneal spaces. Most commonly, periappendiceal and pelvic abscesses arise from a perforation of the appendix. Transmural

inflammation with fistula formation can result in intraabdominal abscess formation in children with inflammatory bowel disease.

CLINICAL MANIFESTATIONS

Prolonged fever, anorexia, vomiting, and lassitude suggest the development of an intraabdominal abscess. The peripheral WBC count is elevated, as is the erythrocyte sedimentation rate. With an appendiceal abscess, there is localized tenderness and a palpable mass in the right lower quadrant. A pelvic abscess is suggested by abdominal distention, rectal tenesmus with or without the passage of small-volume mucous stools, and bladder irritability. Rectal examination might reveal a tender mass anteriorly. Subphrenic gas collection, basal atelectasis, elevated hemidiaphragm, and pleural effusion may be present with a subdiaphragmatic abscess. Psoas abscess can develop from extension of infection from a retroperitoneal appendicitis, Crohn disease, perirenal or intrarenal abscess. Abdominal findings may be minimal, and presentation can include a limp, hip pain, and fever. Ultrasound examination, CT scanning, and MRI may be used to localize intraabdominal abscesses; MRI gives the best resolution of disease involvement.

TREATMENT

An abscess should be drained and appropriate antibiotic therapy provided. Drainage can be performed under radiologic control (ultrasonogram or CT guidance) and an indwelling drainage catheter left in place or surgically depending on location of abscess. Initial broad-spectrum antibiotic coverage such as a combination of ampicillin, gentamicin, and clindamycin or ciprofloxacin and metronidazole should be started and can be modified depending on the results of sensitivity testing. The treatment of appendiceal rupture complicated by abscess formation may be problematic because intestinal phlegmon formation can make surgical resection more difficult. Intensive antibiotic therapy for 4-6 wk followed by an interval appendectomy is often the treatment course followed.

Epigastric Hernia

John J. Aiken and Keith T. Oldham

Epigastric hernias are ventral hernias in the midline of the abdominal wall between the xiphoid and the umbilicus. Epigastric hernias result from defects in the decussating fibers of the linea alba and are more likely congenital than acquired. Because most epigastric hernias are small and asymptomatic, the true incidence is unknown, but the reported incidence in childhood varies from <1% to as high as 5%. Epigastric hernias may be single or multiple and are 2-3 times more common in males than females. The defect typically contains only preperitoneal fat without a peritoneal sac or abdominal viscera. Epigastric (incisional) hernias can occur in a previous incision site or be associated with ventricular-peritoneal shunts.

CLINICAL PRESENTATION

Epigastric hernias typically appear in young children as a visible or palpable mass in the midline, between the umbilicus and the xiphoid, noted by the parents or primary care practitioner. The mass is almost always small (<1 cm) and asymptomatic. The mass is typically present at all times but most apparent at times of irritability or straining. Occasionally, the mass is intermittent and the child relates pain localized to the site of the hernia. Physical examination demonstrates a firm mass, directly in the midline, anywhere between the umbilicus and the xiphoid. Epigastric hernias typically contain only preperitoneal fat and are not reducible because of the small size of the fascial defect. Rarely, a fascial defect is noted without a palpable mass. The mass may be intermittent if the fat reduces with relaxation of the abdominal muscles. Herniation of intestines or abdominal viscera in an epigastric hernia would be exceptionally rare. The mass may be tender to examination, but strangulation of the hernia contents is uncommon. Physical examination is almost always diagnostic and imaging studies are unnecessary.

The natural history of epigastric hernias is for gradual enlargement over time as intermittently more preperitoneal fat is extruded through the defect at times of straining or increased intraabdominal pressure. Left untreated, the defect can enlarge and allow herniation of intraabdominal viscera within a peritoneal sac. Epigastric hernias do not resolve spontaneously, and therefore operative repair is the recommended treatment.

The site should be carefully marked preoperatively because the mass and defect can be difficult to localize after induction of anesthesia. A limited transverse incision is made over the mass and dissection is performed to delineate the edges of the fascial defect. If herniated fat is present, it is dissected free of the subcutaneous tissues and can be reduced or ligated and excised. The defect is closed using absorbable suture. The skin is closed with an absorbable subcuticular suture. Postoperative complications are rare and the recurrence rate is low.

372.1 Incisional Hernia

John J. Aiken and Keith T. Oldham

Hernia formation at the site of a previous laparotomy is uncommon in childhood. Factors associated with an increased risk of incisional hernia include increased intraabdominal pressure, wound infection, and midline incision. Transverse abdominal incisions are favored because of their increased strength and blood supply, which reduce the likelihood of wound infection and incisional hernia. Although most incisional hernias require repair, operation should be deferred until the child is in optimal medical condition. Some incisional hernias resolve, especially those occurring in infants. Some recommend elastic bandaging to discourage enlargement of the hernia and to promote spontaneous healing. Newborns with abdominal wall defects represent the largest group of children with incisional hernias. Initial management should be conservative, with repair deferred until about 1 yr of age. Incarceration is very uncommon but is an indication for prompt repair.

Respiratory System

PART XIX

Section 1

Development and Function

Chapter 373 Respiratory Pathophysiology and Regulation

Ashok P. Sarnaik, Sabrina M. Heidemann, and Jeff A. Clark

The respiratory system serves to supply sufficient oxygen to meet metabolic demands and remove carbon dioxide. Abnormalities in any of the multiple processes (including ventilation, perfusion, and diffusion) that are involved in tissue oxygenation and carbon dioxide removal can lead to respiratory failure. The pathophysiologic manifestations of respiratory disease processes are profoundly influenced by age- and growth-dependent changes in the physiology and anatomy of the respiratory control mechanisms, airway dynamics, and lung parenchymal characteristics. Smaller airways, a more compliant chest wall, and poor hypoxic drive render a younger infant more vulnerable compared to an older child with similar severity of disease.

Respiratory distress may be diagnosed from signs such as cyanosis, nasal flaring, grunting, tachypnea, wheezing, chest wall retractions, and stridor. Respiratory failure can be present without respiratory distress; a patient with abnormalities of central nervous system (CNS) or neuromuscular disease or exhaustion might not be able to mount sufficient effort to appear in respiratory distress. A child who appears in respiratory distress might not have a respiratory illness; a patient with primary metabolic acidosis (diabetic ketoacidosis) or CNS excitatory states (encephalitis) can present in severe respiratory distress without respiratory disease.

373.1 Lung Volumes and Capacities in Health and Disease

Ashok P. Sarnaik, Jeff A. Clark, and Sabrina M. Heidemann

Traditionally, lung volumes are measured with a spirogram (Fig. 373-1). **Tidal volume (V_T)** is the amount of air moved in and out of the lungs during each breath; at rest, V_T is normally 6-7 mL/kg body weight. **Inspiratory capacity** is the amount of air inspired by maximum inspiratory effort after tidal expiration. **Expiratory reserve volume** is the amount of air exhaled by maximum expiratory effort after tidal expiration. The volume of gas remaining in the lungs after maximum expiration is **residual volume. Vital capacity** is defined as the amount of air moved in and out of the lungs with maximum inspiration and expiration. Vital capacity, inspiratory capacity, and expiratory reserve volume are decreased in lung pathology but are also effort dependent. **Total lung capacity** is the volume of gas occupying the lungs after maximum inhalation.

Flow volume relationship offers a valuable means at the bedside or in an office setting to detect abnormal pulmonary mechanics and response to therapy with relatively inexpensive and easy-to-use devices. After maximum inhalation, the patient forcefully exhales through a mouthpiece into the device until residual volume is reached followed by maximum inhalation (Fig. 373-2). Flow is plotted against volume. **Maximum forced expiratory flow (FEF_{max})** is generated in the early part of exhalation, and it is a commonly used indicator of airway obstruction in asthma and other obstructive lesions. Provided maximum pressure is generated consistently during exhalation, a decrease in flow is a reflection of increased airway resistance. The total volume exhaled during this maneuver is **forced vital capacity (FVC)**. **Volume exhaled in 1 sec** is referred to as **FEV_1**. FEV_1/FVC is expressed as a percentage

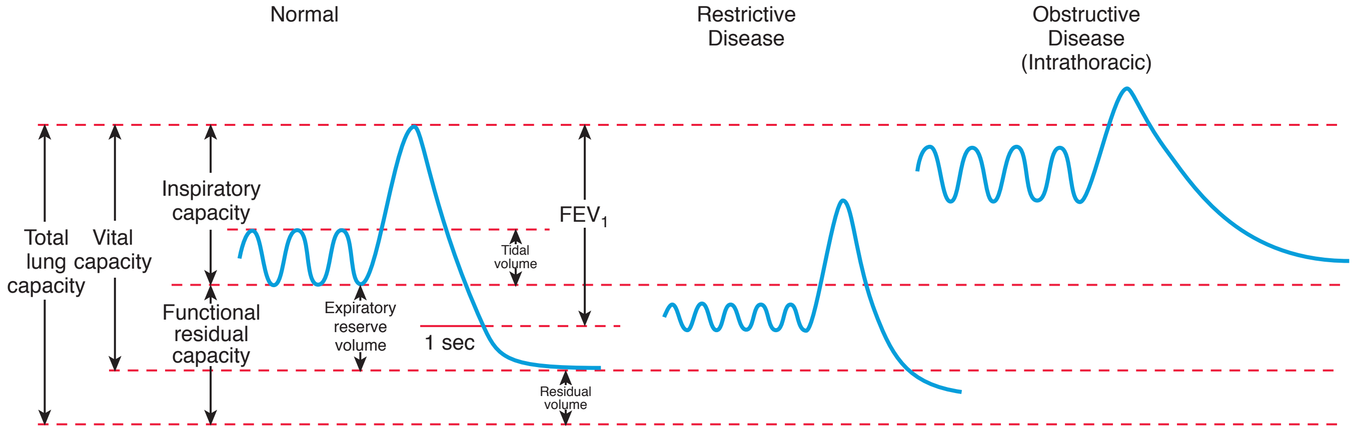

Figure 373-1 Spirogram showing lung volumes and capacities. FEV_1 is the maximum volume exhaled in 1 sec after maximum inspiration. Restrictive diseases are usually associated with decreased lung volumes and capacities. Intrathoracic airway obstruction is associated with air trapping and abnormally high functional residual capacity and residual volume. FEV_1 and vital capacity are decreased in both restrictive and obstructive diseases. The ratio of FEV_1 to vital capacity is normal in restrictive disease but decreased in obstructive disease. FEV, forced expiratory volume.

Gozal D: New concepts in abnormalities of respiratory control in children, *Curr Opin Pediatr* 19:305–308, 2004.

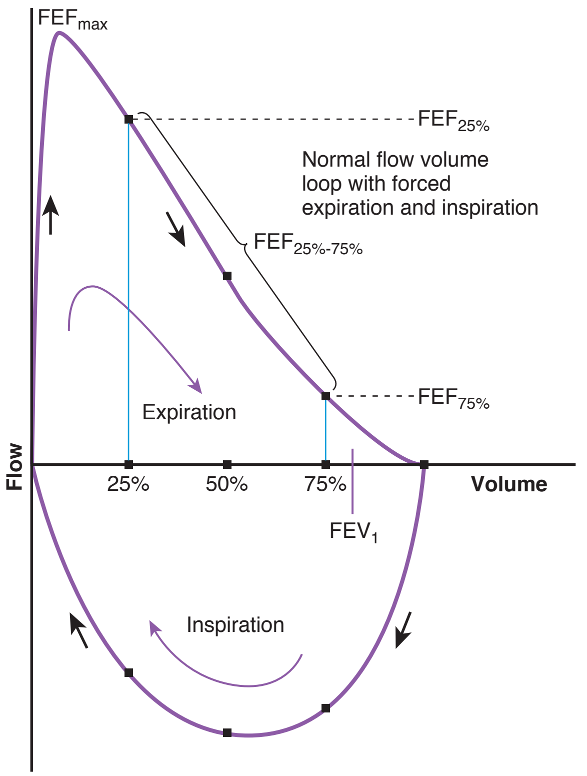

Figure 373-2 **Flow volume loop in a normal person performed after maximal inspiration followed by forced complete expiration and forced complete inhalation.** FEF_{max} represents maximum flow during expiration. This is attained soon after initiation of the expiration. Fall in expiratory flow is gradual until it reaches zero after exhalation is complete. $FEF_{25\%-75\%}$ represents mean flow from 25% ($FEF_{25\%}$) to 75% ($FEF_{75\%}$) of exhaled forced expiratory volume (FEV), also termed *forced vital capacity* (FVC). FEV_1 is amount of volume after 1 sec of forced exhalation. Normally FEV_1 is around 80% of FVC.

of FVC. $FEF_{25\%-75\%}$ is the mean flow between 25% and 75% of FVC and is considered relatively effort independent. Individual values and shapes of flow-volume curves show characteristic changes in obstructive and restrictive respiratory disorders (Fig. 373-3). In intrapulmonary airway obstruction such as asthma or cystic fibrosis, there is a reduction of FEF_{max}, $FEF_{25\%-75\%}$, FVC, and FEV_1/FVC. Also, there is a characteristic concavity in the middle part of the expiratory curve. In restrictive lung disease such as interstitial pneumonia (see Chapter 399.5) and kyphoscoliosis (see Chapter 417.5), FVC is decreased with relative preservation of airflow and FEV_1/FVC. The flow volume curve assumes a vertically oblong shape compared to normal. Changes in shape of the flow volume loop and individual values depend on the type of disease and the extent of severity. Serial determinations provide valuable information regarding disease evolution and response to therapy.

Functional residual capacity (FRC) is the amount of air left in the lungs after tidal expiration. FRC has important pathophysiologic implications. Alveolar gas composition changes during inspiration and expiration. **Alveolar Po_2 (PAo_2)** increases and **alveolar Pco_2 ($PAco_2$)** decreases during inspiration as fresh atmospheric gas enters the lungs. During exhalation, PAo_2 decreases and $PAco_2$ increases as pulmonary capillary blood continues to remove oxygen from and add CO_2 into the alveoli (Fig. 373-4). FRC acts as a buffer, minimizing the changes in PAo_2 and $PAco_2$ during inspiration and expiration. FRC represents the environment available for pulmonary capillary blood for gas exchange at all times.

A decrease in FRC is often encountered in alveolar interstitial diseases and thoracic deformities. The major pathophysiologic consequence of decreased FRC is **hypoxemia**. Reduced FRC results in a sharp decline in PAo_2 during exhalation because a limited volume is available for gas exchange. Po_2 of pulmonary capillary blood therefore falls excessively during exhalation, leading to a decline in **arterial** Po_2 (PAo_2). Any increase in PAo_2 (and therefore Pao_2) during inspiration cannot compensate for the decreased Pao_2 during expiration. The explanation for this lies in the shape of O_2-hemoglobin (Hb) dissociation curve, which is sigmoid shaped (Fig. 373-5). Because most of the oxygen in blood is combined with Hb, it is the percentage of **oxyhemoglobin (So_2)** that gets averaged rather than the Po_2. Although an

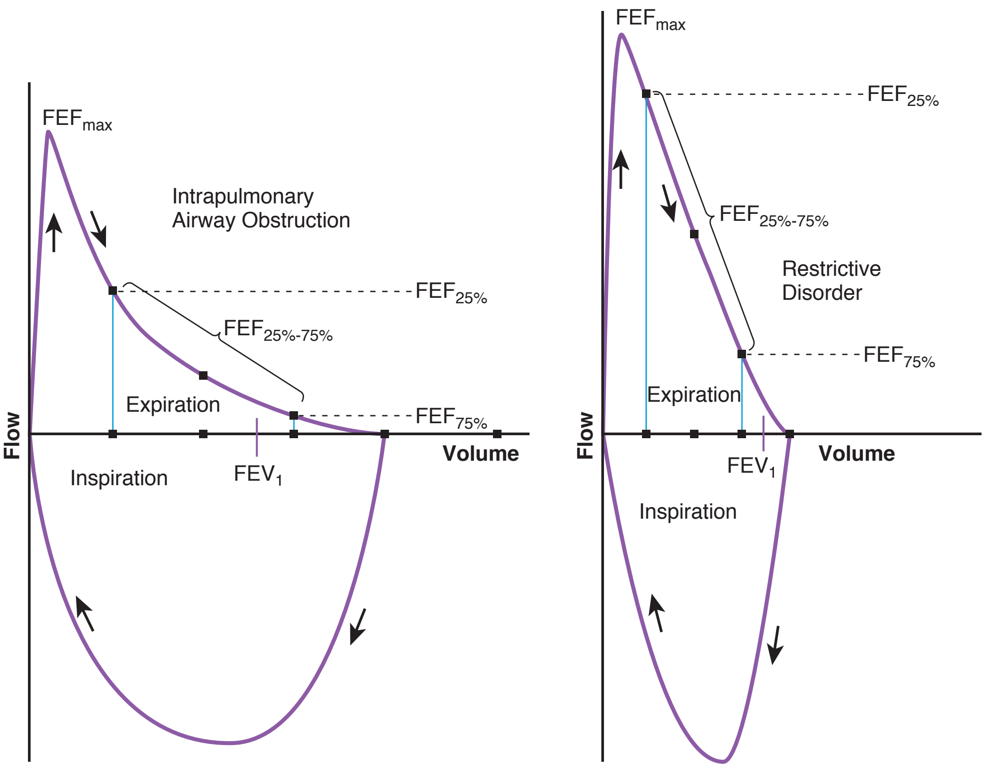

Figure 373-3 **Flow volume loops in intrapulmonary airway obstruction and restrictive disorders.** Note that in intrapulmonary airway obstruction, there is a decrease in FEF_{max}, $FEF_{25\%-75\%}$, and FEV_1/FVC%. The middle part of expiratory loop appears concave. In restrictive disorder, the flow volume loop assumes a more vertically oblong shape with reduction in FVC but not the FEV_1/FVC%. Expiratory and inspiratory flow rates are relatively unaffected. FEF, forced expiratory flow; FEV, forced expiratory volume; FVC, forced vital capacity.

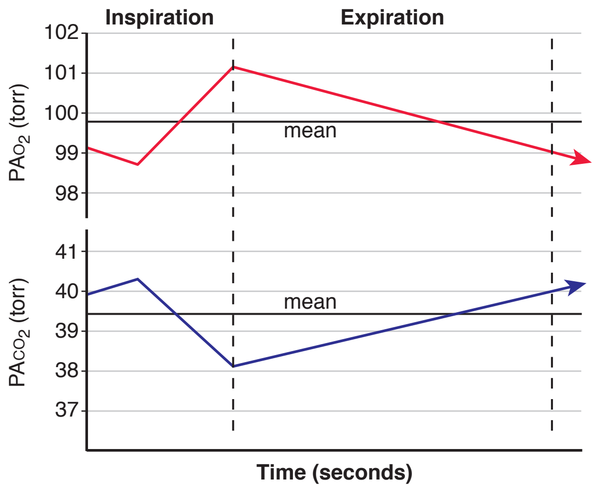

Figure 373-4 **Alveolar P_{O_2} rises and P_{CO_2} falls during inspiration as fresh atmospheric gas is brought into the lungs.** During expiration, the opposite changes occur as pulmonary capillary blood continues to remove O_2 and add CO_2 from the alveoli without atmospheric enrichment. Note that during the early part of inspiration, alveolar P_{O_2} continues to fall and P_{CO_2} continues to rise because of inspiration of the dead space that is occupied by the previously exhaled gas. *(Modified from Comroe JH:* Physiology of respiration, *ed 2, Chicago, 1974, Year Book Medical Publishers, p 12.)*

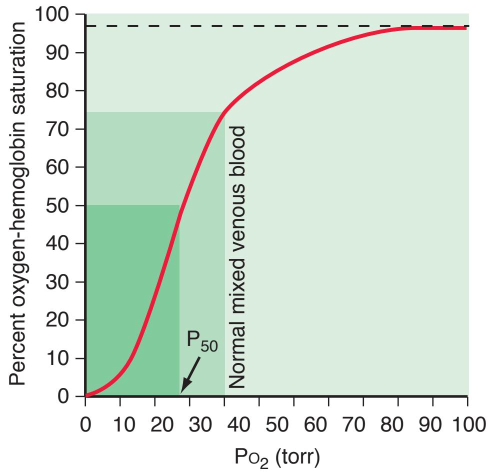

Figure 373-5 **Oxygen-hemoglobin dissociation curve. P_{50} of adult blood is around 27 torr.** Under basal conditions, mixed venous blood has P_{O_2} of 40 torr and oxygen-hemoglobin saturation of 75%. In arterial blood, these values are 100 torr and 97.5%, respectively. Note that there is a steep decline in oxygen-hemoglobin saturation at Pa_{O_2} <50 torr, but relatively little increase in saturation is gained at PO_2 >70 torr.

increase in arterial P_{O_2} cannot increase O_2-Hb saturation >100%, there is a steep desaturation of Hb below a P_{O_2} of 50 torr; thus, decreased S_{O_2} during exhalation as a result of low FRC leads to overall arterial desaturation and hypoxemia. The adverse pathophysiologic consequences of decreased FRC are ameliorated by application of **positive end-expiratory pressure (PEEP)** and increasing the inspiratory time during mechanical ventilation.

The lung pressure–volume relationship is markedly influenced by FRC (Fig. 373-6). Pulmonary compliance is decreased at abnormally low or high FRC.

FRC is abnormally increased in intrathoracic airway obstruction, which results in incomplete exhalation, and abnormally decreased in alveolar-interstitial diseases. At excessively low or high FRC, tidal respiration requires higher inflation pressures compared to normal

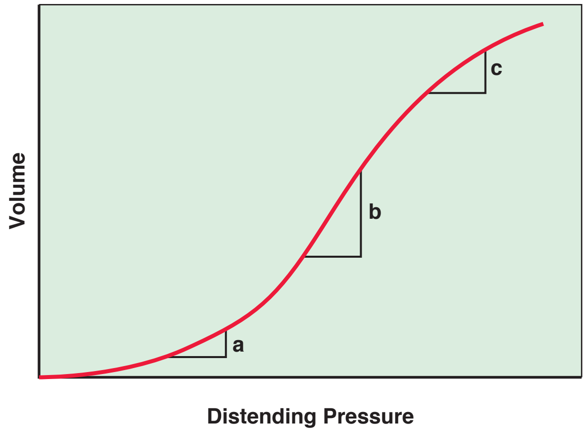

Figure 373-6 **Lung compliance is significantly influenced by the functional residual capacity (FRC).** The same change in pressure is associated with less change in volume when FRC is abnormally decreased *(a)* or abnormally increased *(c)* compared to the normal state *(b)*.

FRC. Abnormalities of FRC result in increased work of breathing with spontaneous respiration and increased barotrauma in mechanical ventilation.

373.2 Chest Wall

Ashok P. Sarnaik, Sabrina M. Heidemann, and Jeff A. Clark

The chest wall and diaphragm of an infant are mechanically disadvantaged compared to that of an adult when required to increase thoracic (and therefore the lung) volume. The infant's ribs are oriented much more horizontally and the diaphragm is flatter and less domed. Consequently, the infant is unable to duplicate the efficiency of upward and outward movement of obliquely oriented ribs and downward displacement of the domed diaphragm in an adult to expand the thoracic capacity. Additionally, the infant's rib cage is softer and thus more compliant compared to an adult's rib cage. Although a soft, highly compliant chest wall is beneficial to a baby in its passage through the birth canal and allows future lung growth, it places the young infant in a vulnerable situation under certain pathologic conditions. Chest wall compliance is a major determinant of FRC. Because the chest wall and the lungs recoil in opposite directions at rest, FRC is reached at the point where the outward elastic recoil of the thoracic cage counterbalances the inward lung recoil. This balance is attained at a lower lung volume in a young infant because of the extremely high thoracic compliance compared to older children (Fig. 373-7). The measured FRC in infants is higher than expected because respiratory muscles of infants maintain the thoracic cage in an inspiratory position at all times. Additionally, some amount of air trapping during expiration occurs in young infants.

The increased chest wall compliance is a distinct disadvantage to the young infant under several pathologic conditions. A decrease in muscle tone, as occurs in *rapid eye movement (REM)* sleep or with CNS depression, allows greater chest wall retraction because of less opposition to the lung recoil; the FRC decreases in such states. The respiratory muscles of infants are poorly equipped to sustain large workloads. They are more easily fatigued than those of older children, limiting their ability to maintain adequate ventilation in lung disease. In diseases of poor lung compliance (atelectasis, pulmonary edema), excessive lung recoil results in greater retraction of the soft chest wall and more loss of FRC than occurs in older children and adults with stiffer chest walls. Increased negative intrathoracic pressure required to overcome airway resistance in upper airway obstruction also produces greater chest wall

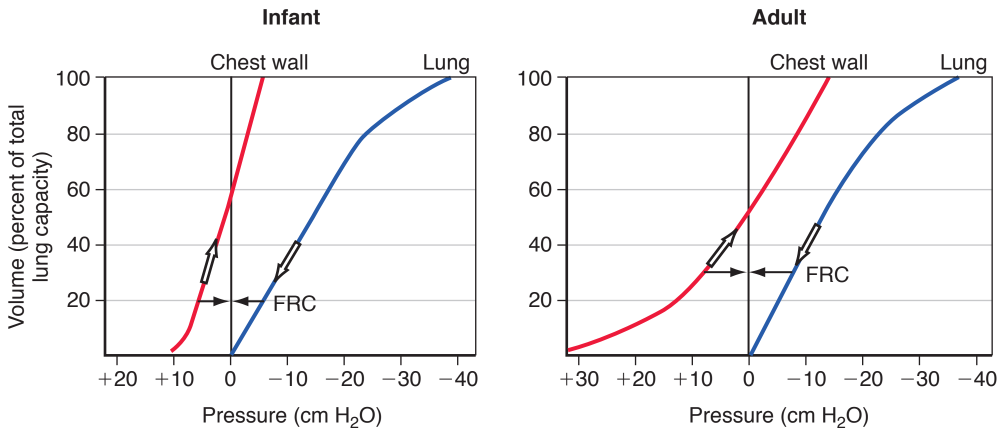

Figure 373-7 Schematic of interaction between chest wall and lung recoil in infants compared to adults. The elastic recoil of a relatively more compliant chest wall is balanced by the lung recoil at a lower volume (FRC) in infants compared to adults. FRC, functional residual capacity.

recoil and reduced FRC in young infants. Application of PEEP is beneficial in such states for stabilizing the chest wall and restoring FRC.

Young infants do not tolerate sustained respiratory loads as well as older children and adults. Respiratory muscle ontogeny is characterized by changes in the composition of muscle fiber types in the diaphragm and intercostals throughout infancy. Type I fibers are slow-twitch and high-oxidative in nature, whereas type II fibers are fast-twitch and low-oxidative. Type I fibers have low contractility but are fatigue resistant. Type II fibers have high contractility but are more prone to fatigue. The proportion of type I fibers in the diaphragm and intercostals of premature infants is only around 10%. This increases to around 25% in full-term newborns and around 50% in children older than age 2 yr. Respiratory muscles of premature babies and young infants are therefore more susceptible to fatigue, resulting in earlier decompensation.

Abnormalities of the chest wall are encountered in certain pathologic conditions. Chest wall instability can result from trauma (fractured ribs, thoracotomy) and neuromuscular diseases that lead to intercostal and diaphragmatic muscle weakness. The increased chest wall compliance makes such children more vulnerable to respiratory decompensation when faced with similar pulmonary pathology compared to older children and adults with stiffer chest walls. Children with rigid, noncompliant chest wall (asphyxiating thoracic dystrophy of Jeune [see Chapters 417.3 and 700], achondroplasia [see Chapter 417.4]) have markedly diminished lung volumes and capacities.

Bibliography is available at Expert Consult.

373.3 Pulmonary Mechanics and Work of Breathing in Health and Disease

Ashok P. Sarnaik, Sabrina M. Heidemann, and Jeff A. Clark

The movement of air in and out of the lungs requires a sufficient pressure gradient between alveoli and atmosphere during inspiration and expiration. Part of the pressure gradient is required to overcome the lung and chest wall elastance; another part is needed to overcome airway resistance. **Elastance** refers to the property of a substance to oppose deformation or stretching. It is calculated as a change in pressure (ΔP) divided by change in volume (ΔV). Elastic recoil is a property of a substance that enables it to return to its original state after it is no longer subjected to pressure. **Compliance** ($\Delta V \div \Delta P$) is the reciprocal of elastance. In the context of the pulmonary parenchyma, airways, and the chest wall, the compliance refers to their distensibility. **Resistance** is calculated as the amount of pressure required to generate flow of gas across the airways. Resistance to laminar flow is governed by *Poiseuille's law* stated as:

$$R = 8l\eta \div \Pi r^4$$

where R is resistance, l is length, η is viscosity, and r is the radius. The practical implication of pressure-flow relationship is that airway resistance is inversely proportional to its radius raised to the 4th power. If the airway lumen is decreased in half, the resistance increases 16-fold. Newborns and young infants with their inherently smaller airways are especially prone to marked increase in airway resistance from inflamed tissues and secretions. In diseases in which airway resistance is increased, flow often becomes turbulent. **Turbulence** depends to a great extent on the *Reynolds number* (Re), a dimensionless entity, which is calculated as:

$$Re = 2rvd \div \eta$$

where r is radius, v is velocity, d is density, and η is viscosity. Turbulence in gas flow is most likely to occur when Re exceeds 2000. Resistance to turbulent flow is greatly influenced by density. A low-density gas such as helium-oxygen mixture decreases turbulence in obstructive airway diseases such as viral laryngotracheobronchitis and asthma. Neonates and young infants are predominantly nose breathers and therefore even a minimal amount of nasal obstruction is poorly tolerated.

The diaphragm is the major muscle of respiration. When additional **work of breathing (WOB)** is required, intercostal and other accessory muscles of respirations also contribute to the increased work. The V_T and respiratory rate are adjusted, both in health and disease, to maintain the required minute volume with the least amount of energy expenditure. The total WOB (necessary to create pressure gradients to move air) is divided into 2 parts. The first part is to overcome the lung and chest wall elastance and is referred to as **elastic work (W_{elast})**. The second part is to overcome airway and tissue resistance, and is referred to as **resistive work (W_{resist})**. W_{elast} is directly proportional to V_T, whereas W_{resist} is determined by the rate of airflow and, therefore, the respiratory rate. The total WOB is lowest at a rate of 35-40/min for neonates and 14-16/min for older children and adults. W_{elast} is disproportionately increased in diseases with decreased compliance and W_{resist} is increased in airway obstruction. Consequently, respirations are shallow (low V_T) and rapid in diseases of low compliance and deep and relatively slow (low flow rate) in diseases of increased resistance.

Compared to older children, young infants have disproportionately greater W_{elast} because the negative intrapleural pressure during inspiration causes the retractile (more compliant) chest wall to collapse and pose an impediment to air entry. Young infants increase their respiratory rate with any mechanical abnormality. Other examples of compliant chest wall being a disadvantage include flail chest resulting from

rib fractures, thoracotomy, and neuromuscular weakness. One of the salutary effects of continuous positive airway pressure in such situations is the stabilization of the chest wall. Under normal conditions, the energy cost of WOB contributes to only approximately 2% of total caloric expenditure. In children with chronic lung disease or congestive heart failure the WOB can contribute to as much as 40% of total energy expenditure during physical activity, thus increasing their caloric needs.

Time constant, measured in seconds, is a product of compliance and resistance. It is a reflection of the amount of time required for proximal airway pressure (and therefore volume) to equilibrate with alveolar pressure. It takes 3 time constants for 95%, and 5 time constants for 99% of pressure equilibration to occur. Because intrathoracic airways expand during inspiration and narrow during expiration, expiratory time constant is longer than inspiratory time constant. Diseases characterized by decreased compliance (pneumonia, pulmonary edema, atelectasis) are associated with a shorter time constant and therefore require less time for alveolar inflation and deflation. Diseases associated with increased resistance (asthma, bronchiolitis, aspiration syndromes) have prolonged time constant and therefore require more time for alveolar inflation and deflation. Pathologic alterations in time constants have practical significance during mechanical ventilation. Patients with shorter time constants are best ventilated with relatively smaller tidal volumes and faster rates to minimize peak inflation pressure. In patients with increased airway resistance, a fast respiratory rate (and, therefore, less time) does not allow enough pressure equilibration to occur between the proximal airway and the alveoli. Inadequate inspiratory time results in lower V_T, whereas insufficient exhalation time results in inadvertent PEEP, often referred to as auto-PEEP or intrinsic PEEP. Such patients are best ventilated with relatively slower rates and larger tidal volumes.

Bibliography is available at Expert Consult.

373.4 Airway Dynamics in Health and Disease

Ashok P. Sarnaik, Sabrina M. Heidemann, and Jeff A. Clark

Because the trachea and airways of an infant are much more compliant than those of older children and adults, changes in intrapleural pressure result in much greater changes in airway diameter. The airway can be divided into 3 anatomic parts: the **extrathoracic airway** extends from the nose to the thoracic inlet, the **intrathoracic–extrapulmonary airway** extends from the thoracic inlet to the main stem bronchi, and the **intrapulmonary airway** is within the lung parenchyma. During normal respirations, intrathoracic airways expand in inspiration as intrapleural pressure becomes more negative and narrow in expiration as they return to their baseline at FRC. The changes in diameter are of little significance in normal respiration. In diseases characterized by airway obstruction, much greater changes in intrapleural pressure are required to generate adequate airflow, resulting in greater changes in airway lumen. The changes in the size of airway during respiration are accentuated in young infants with their softer, more compliant airways.

In extrathoracic airway obstruction (choanal atresia [see Chapter 376], retropharyngeal abscess, laryngotracheobronchitis [see Chapter 385]), the high negative intrapleural pressure during inspiration is transmitted up to the site of obstruction, after which there is a rapid dissipation of pressure. Therefore, the extrathoracic airway below the site of obstruction has markedly increased negative pressure inside, resulting in its collapse, which makes the obstruction worse (Fig. 373-8*A*). This produces inspiratory difficulty, prolongation of inspiration, and inspiratory stridor. Also, the increased negative intrapleural pressure results in chest wall retractions. During expiration, the increased positive intrapleural pressure is again transmitted up the airways to the site of obstruction, leading to a distention of the extrathoracic airway and amelioration of obstruction (Fig. 373-8*B*).

Because of the increased positive intrapleural pressure during exhalation, the chest wall tends to bulge out, which produces the **classic paradoxical respiration,** in which the chest retracts during inspiration and bulges out during expiration. The younger the child, the softer is the chest wall and the more marked is the paradoxical respiration of extrathoracic airway obstruction. A pattern of seesaw respiration may also be evident in newborns and young infants as the compliant chest wall is sucked in and the abdomen bulges out during inspiration, with the converse happening during expiration.

In obstruction of intrathoracic–extrapulmonary airway (vascular ring [see Chapter 386.8], mediastinal tumors) and intrapulmonary airway (asthma, bronchiolitis), the increased negative intrapleural pressure results in a distention of intrathoracic airways during inspiration, thus providing some relief from obstruction (Fig. 373-9*A*).

During expiration, the increased positive intrathoracic pressure is transmitted up to the site of obstruction, after which it dissipates rapidly. The intrathoracic airway above the site of obstruction is

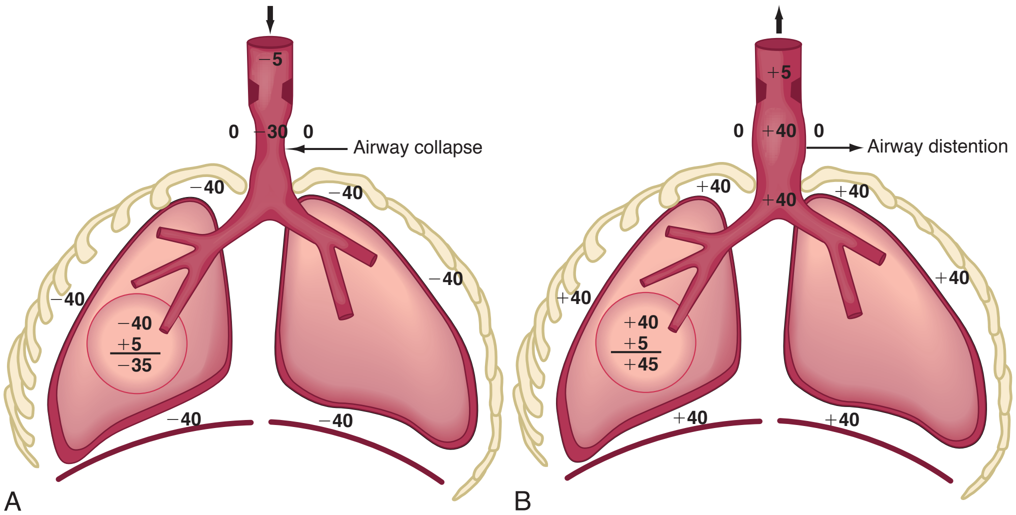

Figure 373-8 A, In extrathoracic airway obstruction, the increased negative pressure during inspiration is transmitted up to the site of obstruction. This results in collapse of the extrathoracic airway below the site of obstruction, making the obstruction worse during inspiration. Note that the pressures are compared to the atmospheric pressure, which is traditionally represented as 0 cm. Terminal airway pressure is calculated as intrapleural pressure plus lung recoil pressure. Lung recoil pressure is arbitrarily chosen as 5 cm for the sake of simplicity. **B,** During expiration, the positive pressure below the site of obstruction results in distention of extrathoracic airway and amelioration of symptoms.

Bibliography

Polla B, D'Antona G, Bottinelli R, et al: Respiratory muscle fibres: specialisation and plasticity, *Thorax* 59:808–817, 2004.

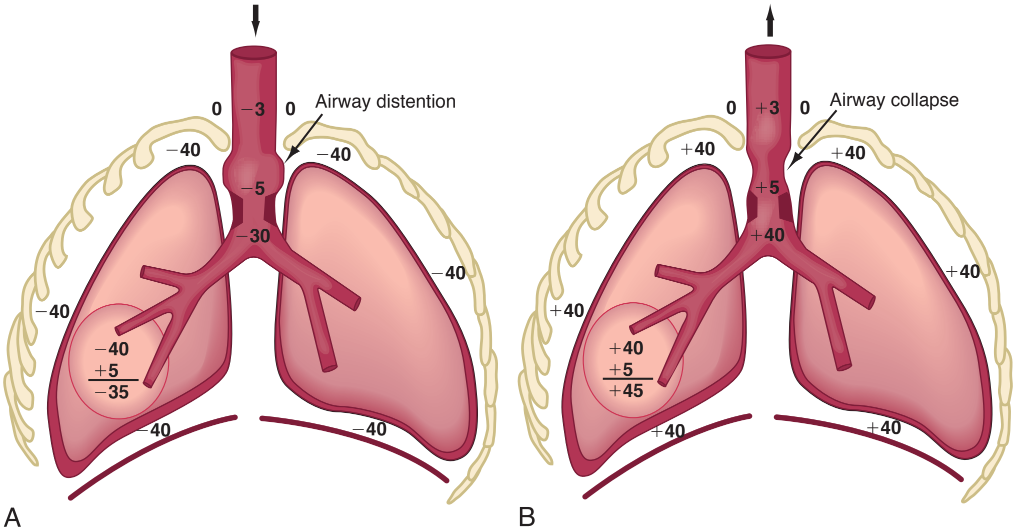

Figure 373-9 **A,** In intrathoracic–extrapulmonary airway obstruction, the increased negative pressure during inspiration is transmitted up to the site of obstruction. This results in the distention of the intrathoracic airway above the lesion because it is surrounded by an even greater negative intrapleural pressure. **B,** During expiration, the increased positive airway pressure rapidly dissipates above the obstruction. Consequently, there is a collapse of the intrathoracic airway above the obstruction as it is subjected to markedly increased positive intrapleural pressure, making the obstruction worse during expiration.

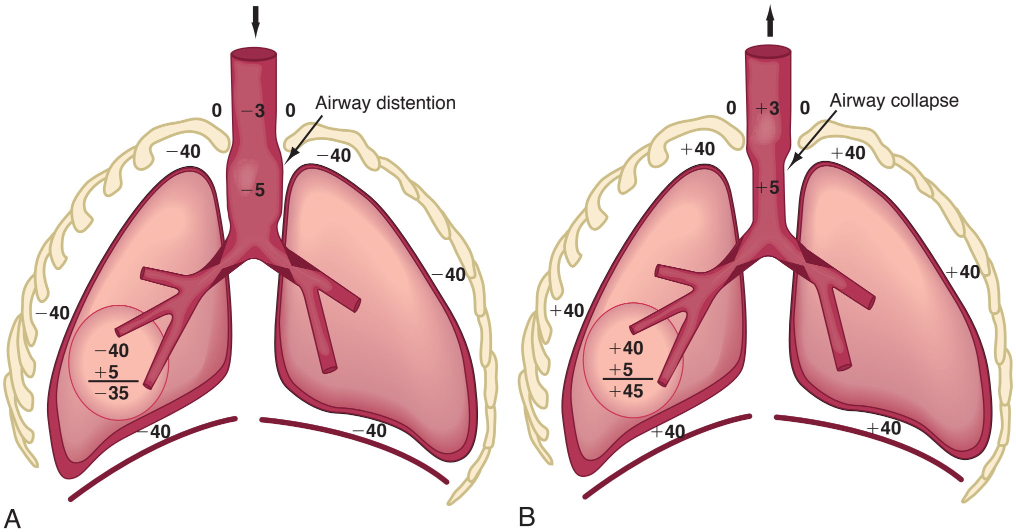

Figure 373-10 **A** and **B,** In intrapulmonary airway obstruction, even a wider segment of intrathoracic airway is subjected to pressure changes compared to those observed in intrathoracic-extrapulmonary airway obstruction. Such lesions are associated with marked increase in airway obstruction during expiration.

therefore subjected to much greater intrapleural pressure from outside, which cannot be adequately balanced by enough positive pressure inside, resulting in collapse above the site of obstruction (see Fig. 373-9*B*).

The site at which pressures inside and outside the airway during exhalation are equal is referred to as the **equal pressure point**. With intrathoracic airway obstruction, the equal pressure point is shifted distally toward the alveolus, causing airway collapse above. Marked inspiratory and expiratory changes in a young infant's airway lumen above the equal pressure point is often termed *collapsible trachea*. **Tracheal collapse** is often a sign of airway obstruction, and it even contributes to its severity, but it is rarely the primary abnormality. With intrapulmonary airway obstruction, an even wider portion of intrathoracic airway is subjected to pressure swings during inspiration and expiration (Fig. 373-10).

Both intrathoracic–extrapulmonary and intrapulmonary airway obstruction result in increasing difficulty during expiration, prolongation of expiration, and expiratory wheezing. Any airway obstruction within the thorax results in expiratory wheezing.

373.5 Interpretation of Clinical Signs to Localize the Site of Pathology

Ashok P. Sarnaik, Sabrina M. Heidemann, and Jeff A. Clark

The first step in establishing the diagnosis of respiratory disease is appropriate interpretation of clinical findings. Respiratory distress can occur without respiratory disease, and severe respiratory failure can be present without significant respiratory distress. Diseases characterized by CNS excitation, such as encephalitis, and neuroexcitatory drugs are

Bibliography

Polgar G, Weng T: The functional development of the respiratory system from the period of gestation to adulthood, *Am Rev Respir Dis* 120:625–695, 1979.

associated with central neurogenic hyperventilation. Similarly, diseases that produce metabolic acidosis, such as diabetic ketoacidosis, salicylism, and shock, result in hyperventilation as a compensatory response. Patients in either group could be considered clinically to have respiratory distress; they are distinguished from patients with respiratory disease by their increased V_T as well as the respiratory rate. Their blood gas values reflect a low $Paco_2$ and a normal Pao_2. Patients with neuromuscular diseases, such as Guillain-Barré syndrome or myasthenia gravis, and those with an abnormal respiratory drive can develop severe respiratory failure but are not able to mount sufficient effort to appear in respiratory distress. In these patients, respirations are ineffective or can even appear normal in the presence of respiratory acidosis and hypoxemia.

The rate and depth of respiration and the presence of retractions, stridor, wheezing, and grunting are valuable signs in localizing the site of respiratory pathology (Table 373-1 and Fig. 373-11). Rapid and shallow respirations (**tachypnea**) are characteristic of parenchymal pathology, in which the elastic WOB is increased disproportionately to the resistive WOB. Chest wall, intercostal, and suprasternal **retractions** are most striking, with increased negative intrathoracic pressure during inspiration. This occurs in extrathoracic airway obstruction as well as diseases of decreased compliance. Inspiratory **stridor** is a hallmark of extrathoracic airway obstruction. Expiratory **wheezing** is characteristic of intrathoracic airway obstruction, either extrapulmonary or intrapulmonary. **Grunting** is produced by expiration against a partially closed glottis and is an attempt to maintain positive airway pressure during expiration for as long as possible. Such prolongation of positive pressure is most beneficial in alveolar diseases that produce widespread loss of FRC, such as in pulmonary edema, hyaline membrane disease, and pneumonia. Grunting is also effective in small airway obstruction (bronchiolitis) to maintain a higher positive pressure in the airway during expiration, decreasing the airway collapse.

Grunting	±	±	++	++++

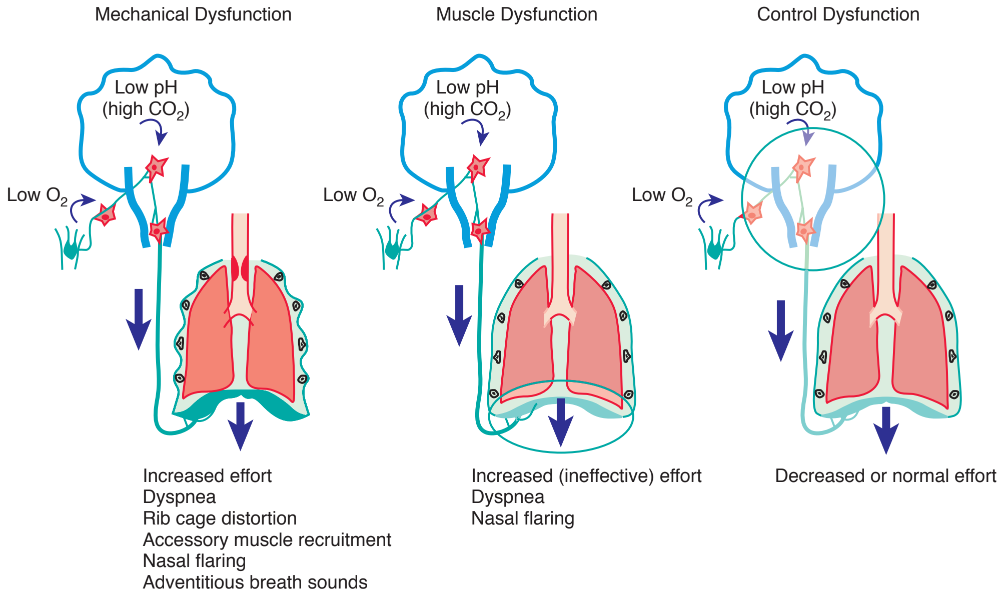

Figure 373-11 Presentation profiles of respiratory failure in childhood. When a mechanical dysfunction is present (by far, the most common circumstance), arterial hypoxemia and hypercapnia (and hence, pH) are sensed by peripheral (carotid bodies) and central (medullary) chemoreceptors. After being integrated with other sensory information from the lungs and chest wall, chemoreceptor activation triggers an increase in the neural output to the respiratory muscles *(vertical arrows)*, which results in the physical signs that characterize respiratory distress. When the problem resides with the respiratory muscles (or their innervation), the same increase in neural output occurs *(arrow)*, but the respiratory muscles cannot increase their effort as demanded; therefore, the physical signs of distress are more subtle. Finally, when the control of breathing is itself affected by disease, the neural response to hypoxemia and hypercapnia is absent or blunted and the gas exchange abnormalities are not accompanied by respiratory distress.

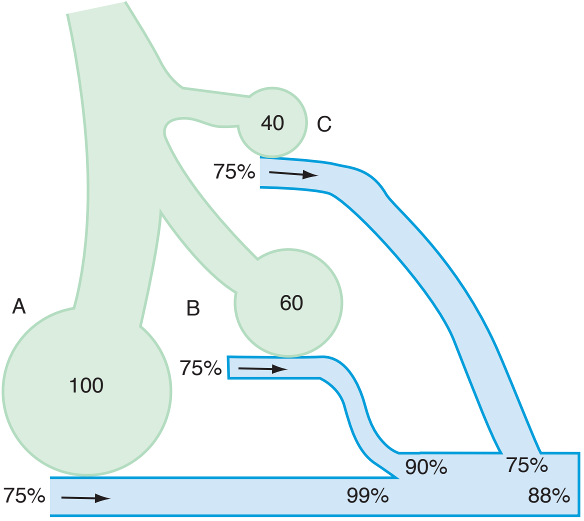

Figure 373-12 **Diagram demonstrating the effects of decreased ventilation–perfusion ratios on arterial oxygenation in the lungs.** Three alveolar–capillary units are illustrated. Unit A has normal ventilation and an alveolar PO_2 of 100 mm Hg (shown by the number in the middle of the space). The blood that circulates through this unit raises its oxygen saturation from 75% (the saturation of mixed venous blood) to 99%. Unit B has a lower ventilation–perfusion ratio and a lower alveolar PO_2 of 60 mm Hg. The blood that circulates through this unit reaches a saturation of only 90%. Finally, unit C is not ventilated at all. Its alveolar PO_2 is equivalent to that of the venous blood, which travels through the unit unaltered. The oxygen saturation of the arterial blood reflects the weighted contributions of these 3 units. If it is assumed that each unit has the same blood flow, the arterial blood would have a saturation of only 88%. Ventilation–perfusion mismatch is the most common mechanism of arterial hypoxemia in lung disease. Supplemental oxygen increases the arterial PO_2 by raising the alveolar PO_2 in lung units that, like B, have a ventilation–perfusion ratio >0.

parts (the upper lobes in upright position) of the lung are subjected to greater negative intrapleural pressure during tidal respiration and are kept relatively more inflated compared to the dependent alveoli and airways (the lower lobes in upright position). The nondependent alveoli are less compliant because they are already more inflated. During tidal inspiration, ventilation therefore occurs preferentially in the dependent portions of the lung that are more amenable to expansion. Although perfusion is also greater in the dependent portions of the lung because of greater pulmonary arterial hydrostatic pressure from gravity, the increase in perfusion is greater than the increase in ventilation in the dependent portions of the lung. Thus, the ratios favor ventilation in the nondependent portions and perfusion in the dependent portions. Because the airways in the dependent portion of the lung are narrower, they close earlier during expiration. The lung volume at which the dependent airways start to close is referred to as the **closing capacity.** In normal children, the FRC is greater than the closing capacity**.** During tidal respiration, airways remain patent both in the dependent and the nondependent portions of the lung. In newborns, the closing capacity is greater than the FRC, resulting in perfusion of poorly ventilated alveoli during tidal respiration; therefore, normal neonates have a lower Pao_2 compared to older children.

The relationship is adversely affected in a variety of pathophysiologic states (Fig. 373-12). Air movement in areas that are poorly perfused is referred to as **dead space ventilation.** Examples of dead space ventilation include pulmonary thromboembolism and hypovolemia. Perfusion of poorly ventilated alveoli is referred to as **intrapulmonary right-to-left shunting** or **venous admixture**. Examples include pneumonia, asthma, and hyaline membrane disease. In intrapulmonary airway obstruction, the closing capacity is abnormally increased and can exceed the FRC. In such situations, perfusion of poorly ventilated alveoli during tidal respiration results in venous admixture.

373.7 Gas Exchange in Health and Disease

Ashok P. Sarnaik, Sabrina M. Heidemann, and Jeff A. Clark

The main function of the respiratory system is to remove carbon dioxide from and add oxygen to the systemic venous blood brought to the lung. The composition of the inspired gas, ventilation, perfusion, diffusion, and tissue metabolism have a significant influence on the arterial blood gases.

The total pressure of the atmosphere at sea level is 760 torr. With increasing altitude, the atmospheric pressure decreases. The total atmospheric pressure is equal to the sum of partial pressures exerted by each of its component gases. Alveolar air is 100% humidified and, therefore, for alveolar gas calculations, the inspired gas is also presumed to be 100% humidified. At a temperature of 37°C (98.6°F) and 100% humidity, water vapor exerts pressure of 47 torr, regardless of altitude. In a natural setting, the atmosphere consists of 20.93% oxygen. **Partial pressure of oxygen in inspired gas (Pio_2)** at sea level is therefore (760 − 47) × 20.93% = 149 torr. When breathing 40% oxygen at sea level, Pio_2 is (760 − 47) × 40% = 285 torr. At higher altitudes, breathing different concentrations of oxygen, Pio_2 is less than at sea level, depending on the prevalent atmospheric pressures. In Denver (altitude of 5,000 feet and barometric pressure of 632 torr), Pio_2 in room air is (632 − 47) × 20.93% = 122 torr, and in 40% oxygen, it is (632 − 47) × 40% = 234 torr.

Minute volume is a product of V_T and respiratory rate. Part of the V_T occupies the conducting airways (anatomic dead space), which does not contribute to gas exchange in the alveoli. **Alveolar ventilation** is the volume of atmospheric air entering the alveoli and is calculated as (V_T − dead space) × respiratory rate. Alveolar ventilation is inversely proportional to arterial Pco_2 ($Paco_2$). When alveolar ventilation is halved, $Paco_2$ is doubled. Conversely, doubling of alveolar ventilation decreases $Paco_2$ by 50%. **Alveolar Po_2 (Pao_2)** is calculated by the **alveolar air equation** as follows:

$$PAo_2 = PiO_2 - (PAco_2 \div R)$$

where R is the respiratory quotient. For practical purposes, $PAco_2$ is substituted by **arterial Pco_2** ($Paco_2$) and R is assumed to be 0.8. According to the alveolar air equation, for a given Pio_2, a rise in $Paco_2$ of 10 torr results in a decrease in PAo_2 by 10 ÷ 0.8 or 10 × 1.25 or 12.5 torr. Thus, proportionately inverse changes in PAo_2 occur to the extent of 1.25× the changes in $PAco_2$ (or $Paco_2$).

After the alveolar gas composition is determined by the inspired gas conditions and process of ventilation, gas exchange occurs by the process of diffusion and equilibration of alveolar gas with pulmonary capillary blood. Diffusion depends on the alveolar capillary barrier and amount of available time for equilibration. In health, the equilibration of alveolar gas and pulmonary capillary blood is complete for both oxygen and carbon dioxide. In diseases in which alveolar capillary barrier is abnormally increased (alveolar interstitial diseases) and/or when the time available for equilibration is decreased (increased blood flow velocity), diffusion is incomplete. Because of its greater solubility in liquid medium, carbon dioxide is 20 times more diffusible than oxygen. Therefore, diseases with diffusion defects are characterized by marked **alveolar-arterial oxygen (A-aO_2)** gradients and hypoxemia. Significant elevation of CO_2 does not occur as a result of a diffusion defect unless there is coexistent hypoventilation.

Venous blood brought to the lungs is "arterialized" after diffusion is complete. After complete arterialization, the pulmonary capillary blood should have the same Po_2 and Pco_2 as in the alveoli. The arterial blood gas composition is different from that in the alveoli, even in normal conditions because there is a certain amount of dead space ventilation as well as venous admixture in a normal lung. Dead space ventilation results in a higher $Paco_2$ than $PAco_2$, whereas venous admixture or right-to-left shunting results in a lower Pao_2 compared to the alveolar gas composition (see Fig. 373-12). Pao_2 is a reflection of the amount of oxygen dissolved in blood, which is a relatively minor component of total blood oxygen content. For every 100 torr Po_2, there is 0.3 mL of dissolved O_2 in 100 mL of blood. The total blood oxygen

Bibliography

West JB: *Respiratory physiology: the essentials*, ed 8, Baltimore, 2008, Lippincott Williams and Wilkins.

content is composed of the dissolved oxygen and the oxygen bound to hemoglobin. Each gram of hemoglobin carries 1.34 mL of O_2 when 100% saturated with oxygen. Thus, 15 g of hemoglobin carries 20.1 mL of oxygen. **Arterial oxygen content (Cao_2)**, expressed as mL O_2/dL blood, can be calculated as ($Pao_2 \times 0.003$) + (Hb × 1.34 × So_2), where Hb is grams of Hb per deciliter of blood and So_2 is percentage of oxyhemoglobin saturation. The relationship of Po_2 and the amount of oxygen carried by the hemoglobin is the basis of the O_2-Hb dissociation curve (see Fig. 373-5). The Po_2 at which hemoglobin is 50% saturated is referred to as P_{50}. At a normal pH, hemoglobin is 94% saturated at Po_2 of 70, and little further gain in saturation is accomplished at a higher Po_2. At Po_2 <50, there is a steep decline in saturation and therefore the oxygen content.

Oxygen delivery to the tissues is a product of oxygen content and cardiac output. When hemoglobin is near 100% saturated, the blood contains approximately 20 mL oxygen per 100 mL or 200 mL/L. In a healthy adult, the cardiac output is approximately 5 L/min, oxygen delivery 1,000 mL/min, and oxygen consumption 250 mL/min. Mixed venous blood returning to the heart has a Po_2 of 40 torr and is 75% saturated with oxygen. Blood oxygen content, cardiac output, and oxygen consumption are important determinants of mixed venous oxygen saturation. Given a steady-state blood oxygen content and oxygen consumption, the mixed venous saturation is an important indicator of cardiac output. A declining mixed venous saturation in such a state indicates decreasing cardiac output.

373.8 Interpretation of Blood Gases

Ashok P. Sarnaik, Sabrina M. Heidemann, and Jeff A. Clark

Clinical observations and interpretation of blood gas values are critical in localizing the site of the lesion and estimating its severity (Table 373-2). In airway obstruction above the carina (subglottic stenosis, vascular ring), blood gases reflect overall alveolar hypoventilation. This is manifested by an elevated $PAco_2$ and a proportionate decrease in Pao_2 as determined by the alveolar air equation. A rise in $Paco_2$ of 20 torr decreases Pao_2 by 20 × 1.25 or 25 torr. In the absence of significant parenchymal disease and intrapulmonary shunting, such lesions respond very well to supplemental oxygen in reversing hypoxemia. Similar blood gas values, demonstrating alveolar hypoventilation and response to supplemental oxygen, are observed in patients with a depressed respiratory center and ineffective neuromuscular function, resulting in respiratory insufficiency. Such patients can be easily distinguished from those with airway obstruction by their poor respiratory effort.

In intrapulmonary airway obstruction (asthma, bronchiolitis), blood gases reflect ventilation-perfusion imbalance and venous admixture. In these diseases, the obstruction is not uniform throughout the lungs, resulting in areas that are hyperventilated and others that are hypoventilated. Pulmonary capillary blood coming from hyperventilated areas has a higher Po_2 and lower Pco_2, whereas that coming from hypoventilated regions has a lower Po_2 and higher Pco_2. A lower blood Pco_2 can compensate for the higher Pco_2 because the Hb-CO_2 dissociation curve is relatively linear. In mild disease, the hyperventilated areas predominate, resulting in hypocarbia. An elevated Pao_2 in hyperventilated areas cannot compensate for the decreased Pao_2 in hypoventilated areas because of the shape of the O_2-Hb dissociation curve. This results in venous admixture, arterial desaturation, and decreased Pao_2 (see Fig. 373-12). With increasing disease severity, more areas become hypoventilated, resulting in normalization of $Paco_2$ with a further decrease in Pao_2. A normal or slightly elevated $Paco_2$ in asthma should be viewed with concern as a potential indicator of impending respiratory failure. In severe intrapulmonary airway obstruction, hypoventilated areas predominate, leading to hypercarbia, respiratory acidosis, and hypoxemia. The degree to which supplemental oxygenation raises Pao_2 depends on the severity of the illness and the degree of venous admixture.

In alveolar and interstitial diseases, blood gas values reflect both intrapulmonary right-to-left shunting and a diffusion barrier. Hypoxemia is a hallmark of such conditions occurring early in the disease process. $Paco_2$ is either normal or decreased. An increase in $Paco_2$ is observed only later in the course, as muscle fatigue and exhaustion result in hypoventilation. Response to supplemental oxygen is relatively poor with shunting and diffusion disorders compared to other lesions.

Most clinical entities present with mixed lesions. A child with a vascular ring might also have an area of atelectasis; the arterial blood gas reflects both processes. The blood gas values reflect the more dominant lesion.

373.9 Pulmonary Vasculature in Health and Disease

Ashok P. Sarnaik, Sabrina M. Heidemann, and Jeff A. Clark

The tunica media of the pulmonary arteries of the fetus become more muscular in the last trimester of pregnancy (see Chapter 101.1). Up to 90% of the systemic venous return is shunted away from the pulmonary arterial circulation to the systemic arterial circulation through the foramen ovale and the ductus arteriosus. After birth, with functional closure of the foramen ovale and the ductus arteriosus, and dilation of the pulmonary arterial circulation with consequent decrease in **pulmonary vascular resistance** (**PVR**), all of the right ventricular output passes through the lung. The PVR is approximately 50% of the systemic arterial resistance 3 days after birth. In the next several wk after birth as pulmonary arterial musculature in the tunica media involutes, there is a further decline in PVR and therefore in pulmonary artery pressure. Two to 3 mo after birth, the PVR and the pulmonary artery pressure

Table 373-2 Interpretation of Arterial Blood Gas Values

LESION	EFFECT	TYPICAL ABG
Central (above the carina) airway obstruction, or Depressed respiratory center, or Ineffective neuromuscular function	Uniform alveolar hypoventilation	Early increase in Pco_2 Proportionate decrease in Po_2 depending on alveolar air equation Response to supplemental oxygen: Excellent
Intrapulmonary airway obstruction	Venous admixture $\dot{V}/\dot{Q}$ mismatch	Mild: ↓ Pco_2, ↓ Po_2 Moderate: "normal" Pco_2, ↓↓ Po_2 Severe: ↑↑ Pco_2, ↓↓↓ Po_2 Response to supplemental oxygen: good
Alveolar–interstitial pathology	Diffusion defect R → L shunt	Early decrease in Po_2 depending on severity Normal or low Pco_2, ↑ Pco_2 if fatigue develops Response to supplemental oxygen: fair to poor

ABG, arterial blood gas; $\dot{V}/\dot{Q}$, ventilation–perfusion.

are approximately 15% of the systemic values, a relationship that exists through childhood and adolescence. Pulmonary vasculature constricts in response to hypoxemia, acidosis, and hypercarbia and dilates with increased alveolar and arterial Po_2, alkalosis, and hypocarbia. Younger infants, with their relatively muscular pulmonary arteries, are especially susceptible to pulmonary vasoconstrictive stimuli.

Failure of the pulmonary arterial circulation to dilate after birth results in **persistent pulmonary hypertension of the newborn** (see Chapter 101.7). Because of the persistently high PVR, the systemic venous blood returning to the right side of the heart continues to be shunted across the foramen ovale and the ductus arteriosus to the systemic arterial circulation, leading to a vicious cycle of hypoxemia, acidosis, and further pulmonary vasoconstriction.

The relatively high PVR opposes excessive left-to-right shunting in full-term neonates with ventricular septal defect and patent ductus arteriosus (see Chapter 426). Such infants do not usually manifest heart failure until 2-3 mo after birth, when PVR has sufficiently declined. Premature infants who have lesions capable of left-to-right shunting are susceptible to developing heart failure earlier in life because of less musculature in pulmonary artery tunica media and, therefore, a lower PVR. The gradual physiologic decline in PVR over the 1st 2-3 mo of life also explains how infants with anomalous left coronary artery arising from the pulmonary artery are asymptomatic at birth but present with signs of coronary insufficiency when PVR has fallen sufficiently to critically decrease coronary perfusion. Persistent and long-term left-to-right shunting carries the risk of developing secondary pulmonary vascular disease characterized by the postnatal development of medial muscular hypertrophy followed by intimal proliferation and increased PVR. Early changes in pulmonary vasculature are reversible with correction of the congenital heart defect responsible for left-to-right shunting. Advanced pulmonary vascular disease is characterized by irreversible intimal and medial changes. When PVR is increased to suprasystemic levels, right-to-left shunting occurs and is characterized by a cyanotic state (Eisenmenger syndrome), making the heart defect inoperable in the absence of an accompanying lung transplantation (see Chapter 433.2).

Pulmonary hypertension can develop without a well-defined etiology (primary pulmonary hypertension) or as a consequence of an underlying disease (secondary pulmonary hypertension) (see Chapter 433). Adverse effects of pulmonary hypertension are related to an increased right ventricular afterload, decreased cardiac output, and heart failure characterized by increased systemic venous pressure, hepatomegaly, and edema. In an acute situation, right ventricular failure and decreased cardiac output can worsen oxygen delivery and hypoxemia. Right ventricular failure secondary to pulmonary pathology is referred to as **cor pulmonale.** Secondary pulmonary hypertension is a common occurrence in end-stage chronic obstructive pulmonary disease such as cystic fibrosis (see Chapter 403) and bronchopulmonary dysplasia (see Chapter 416). Pulmonary arterial involvement is sometimes encountered in collagen vascular diseases such as scleroderma (see Chapter 160) and dermatomyositis (see Chapter 159). Functional or structural upper airway obstruction can also produce right ventricular failure. Children with marked obesity are also susceptible to chronic alveolar hypoventilation and right heart failure, termed **Pickwickian syndrome.** Treatment of the underlying cause is the first priority in patients with secondary pulmonary hypertension (see Chapter 433). Pulmonary hypertension is diagnosed by cardiac catheterization in order to rule out other pulmonary vascular diseases and to test for pulmonary reactivity. A diagnosis of pulmonary hypertension is a mean pulmonary artery pressure of ≥25 mm Hg at rest with a normal pulmonary capillary wedge pressure of ≤15 mm Hg and increased PVR index of ≥3 Wood units/m^2. Even though the etiologies are different, most of the drugs used to treat this condition in children are adapted from adult studies. Calcium channel blockers, prostanoids (epoprostenol, treprostinil, and iloprost), endothelin receptor antagonists (bosentan, ambrisentan) and phosphodiesterase 5-inhibitors (sildenafil, tadalafil) are some of the agents used for treatment.

373.10 Immune Response of the Lung to Injury

Ashok P. Sarnaik, Sabrina M. Heidemann, and Jeff A. Clark

Local and systemic diseases can potentially induce an inflammatory response in the lung. Local diseases of the lung capable of inducing the inflammatory response include infectious processes, aspiration, asphyxia, pulmonary contusion, and inhalation of chemical irritants; systemic diseases include sepsis, shock, trauma, and cardiopulmonary bypass. This inflammatory response is mediated through the release of cytokines and other mediators. In the lung, alveolar macrophages are the chief architects of the early cytokine response, producing **tumor necrosis factor-α** and **interleukin-1β.** These cytokines are involved in initiating the inflammatory cascade, resulting in the production of other cytokines, prostaglandins, reactive oxygen species, and upregulating cell adhesion molecules, which, in turn, leads to white cell migration into the lung tissue. The pathophysiologic consequences of the inflammatory response include injury to pulmonary capillary endothelium and the alveolar epithelial cells. Various cytokines and eicosanoids produce pulmonary vasoconstriction, resulting in pulmonary hypertension and increased right ventricular afterload. Injury to the capillary endothelium results in increased permeability and exudation of protein-rich fluid into the pulmonary interstitium and alveoli. Cellular debris and fibrin form the characteristic eosinophilic hyaline membranes along the walls of the alveolar duct. There is sloughing of type 1 pneumocytes. Interstitial and alveolar edema results in decreased FRC, diffusion barrier, intrapulmonary right-to-left shunting across poorly ventilating alveoli, and increase in the A-aO_2 gradient. Clinically, A-aO_2 gradient >200 is characterized as *acute lung injury* and a gradient >300 is termed **acute respiratory distress syndrome (ARDS)** (see Chapter 71). The inflammatory response to lung injury changes from the fetus to the adult. The fetus and neonate are more likely to have less of an inflammatory cytokine response as demonstrated by a decrease in tumor necrosis factor-α production when mononuclear cells are stimulated when compared to the adult.

The pediatrician must consider the potential adverse effects of therapeutic interventions such as oxygen, endotracheal intubation, and mechanical ventilation as part of the pathophysiologic consequences of ARDS. High concentrations of inspired oxygen have a risk of pulmonary capillary and epithelial cell injury; the concentration of oxygen below which it can be considered safe has not been established. In addition to the potential for nosocomial pneumonia, mechanical ventilation carries the risk of ventilator-induced lung injury from physical stress applied to terminal airways, alveolar epithelium, and pulmonary capillaries. Excessive V_T can itself result in mechanical disruption capable of perpetuating the inflammatory response. If alveoli are allowed to deflate excessively during exhalation, they are subjected to greater stress injury from alveolar recruitment and derecruitment. The mechanical ventilation strategy aimed at minimizing ventilator-induced lung injury in ARDS includes alveolar recruitment and maintenance of adequate FRC throughout the respiratory cycle with an optimum PEEP, and ventilation with relatively low (6-8 mL/kg) V_T.

373.11 Regulation of Respiration

Ashok P. Sarnaik, Sabrina M. Heidemann, and Jeff A. Clark

The main function of respiration is to maintain normal blood gas homeostasis to match the metabolic needs of the body with the least amount of energy expenditure. Respiratory rate and V_T are regulated by a complex interaction of **controllers, sensors,** and **effectors.** The central respiratory controller consists of a group of neurons in the CNS that receives and integrates the afferent information from sensors and sends motor impulses to effectors to initiate and maintain respiration. Sensors are a variety of receptors located throughout the body. They

gather chemical and physical information that is sent to the controller either to stimulate or to inhibit its activity. Effectors are the various muscles of respiration that, under the influence of controllers, coordinate respiration and move air in and out of the lung at a given V_T and rate. The respiratory regulatory mechanism itself undergoes a significant maturation process from the neonatal period throughout infancy and early childhood. **Sleep states** have the potential for profound influences on the control of respiration.

CENTRAL RESPIRATORY CONTROLLER

Although the respiratory cycle is often viewed as having an active phase (inspiration) and a passive phase (expiration), rhythmic breathing is a complex process controlled by interaction of numerous distinct groups of neurons. Neuronal control of respiration occurs in 3 phases—inspiration (I), early expiration (E1), and late expiration (E2)—and each may be dysfunctional in disease states. The respiratory controller mechanism comprises 2 functionally and anatomically distinct groups of neurons located in the CNS: 1 for **voluntary** and the other for **automatic control**. These areas of respiratory control can function independently but are also capable of interacting with each other.

Voluntary control of respiration resides in the cerebral motor cortex and limbic forebrain structure. Information is received from sensory neurons such as pain, touch, temperature, smell, vision, and emotions, and impulses are sent directly to the respiratory muscles through corticobulbar and corticospinal tracts. Voluntary control of respiration is important for protection from aspiration and inhalation of noxious gases. A certain level of consciousness is necessary to exercise voluntary control of respiration. Patients with CNS injury and toxic or metabolic encephalopathies may lose voluntary control of respirations to varying degrees, depending on the extent of CNS dysfunction.

Automatic control of respiration resides in the brainstem. Central pattern generators (CPGs) are neuronal circuits that generate rhythmic motor output, do not require conscious input, and are responsible for numerous coordinated motor functions such as breathing, swallowing, chewing, walking, and vomiting. The primary CPGs responsible for control of breathing are located in the pons and medulla and include the Bötzinger complex (BotC), pre-Bötzinger complex (pre-BotC), rostral ventral respiratory group and the caudal ventral respiratory group in the medulla, and the Kolliker-Fuse and lateral parabrachial areas in the pons. In addition, an area located adjacent to the facial nerve nucleus, the parafacial respiratory group, is an important modulator of respiration and dysfunction here likely plays a key role in congenital central hypoventilation syndrome (CCHS). Pre-BotC and rostral ventral respiratory group are thought to be the primary sites for inspiratory rhythm generation and BotC and caudal ventral respiratory group are thought to be the primary sites of expiratory rhythm generation under normal circumstances. However, each area is under significant influence from other areas including the nucleus tractus solitus, which is the area responsible for receiving visceral sensor afferents (see below). The genetic mutation responsible for Prader-Willi syndrome is similar to a genetic knockout in mice known to be associated with abnormal development of the pre-BotC and is likely responsible for the abnormal O_2 and CO_2 responsiveness associated with this disease.

CPG areas can also be modulated by neurotransmitters, which can stimulate, inhibit, or modify their activity; they possess receptors for substance P (neurokinin), acetylcholine (nicotinic), glutamate, and opioid μ receptors among others. The embryologic development of these areas is regulated by several genes such as Hox paralogs and Hox-regulating genes *kreisler/mafB* and *Krox20*. A group of neurons located in the lower pons is collectively termed the **apneustic center,** which stimulates pre-BotC, resulting in prolonged inspiratory gasps (apneuses) interrupted by transient expiratory efforts. Another group of neurons in the upper pons, called the *pneumotaxic center,* is involved in inhibiting the activity of pre-BotC. The role of apneustic and pneumotaxic centers is to fine-tune the rhythmic respiratory activity generated by pre-BotC neurons.

Abnormalities of respirations are commonly encountered in CNS dysfunction and have given clues to the role each of these areas plays in the regulation of respiration. Global CNS depression can manifest as slow and shallow respirations with resultant hypoventilation and respiratory acidosis. Bihemispheric and diencephalic pathology can lead to **Cheyne-Stokes respirations,** characterized by periods of apnea interspersed with hyperventilation. Injuries within the rostral brainstem or tegmentum can lead to central neurogenic hyperventilation and respiratory alkalosis. Mid to caudal pontine lesion can result in an apneustic breathing pattern characterized by a prolonged inspiratory pause. Medullary lesions result in ataxic, irregular breathing or apnea.

SENSORS

The primary responsibility of the respiratory system is to maintain a steady and adequate supply of oxygen to the blood and help maintain adequate pH by eliminating CO_2. Even short periods of hypoxemia or acidosis are poorly tolerated, and as such, the body has evolved multiple mechanisms to identify hypoxemia and acidosis/increased CO_2. Various receptors throughout the body are responsible for sensing and sending afferent information that modulates the activity of the central respiratory controller. These receptors are sensory nerve endings that respond to changes in their environment. They are termed either **chemoreceptors** or **mechanoreceptors,** depending on the type of stimulus that is sensed. Chemoreceptors are classified as central or peripheral, depending on their location.

Central chemoreceptors are so termed because of their location within the CNS. Chemoreceptors sense a change in the chemical composition of body fluid to which they are exposed. Central chemoreceptors reside over a wide area that includes the posterior hypothalamus, cerebellum, locus ceruleus, raphe, and multiple nuclei within the brainstem. Central chemoreceptors bathe in the extracellular fluid of the brain and respond to the changes in the H^+ concentration. Information sensing an increase in H^+ concentration stimulates ventilatory response of the controller, whereas a decrease inhibits it. The brain's extracellular fluid, represented by the cerebrospinal fluid (CSF), is separated from the blood by the blood-brain barrier, which is relatively impermeable to H^+ and HCO_3^- ions but is readily permeable to CO_2. A rise in $Paco_2$ is quickly reflected in a similar rise in the CSF. The consequent fall in CSF pH is sensed by the central chemoreceptors, causing stimulation of the controller and increase in ventilation. Changes in $Paco_2$ result in stimulation or inhibition of ventilation by changes in CSF pH. CSF pH in normal conditions is approximately 7.32. Compared to blood, CSF has much less CO_2 buffering capacity because of a much lower protein concentration. Consequently, the change in CSF pH is more pronounced than that in the blood for the same change in $Paco_2$. With a persistent elevation in $Paco_2$, the CSF pH eventually tends to normalize as HCO_3^- equilibrates across the blood-brain barrier. Consequently, patients with chronic obstructive pulmonary disease have a relatively normal CSF pH, and they do not show the ventilatory response that is observed with an acute rise in $Paco_2$. Although O_2 chemosensing has traditionally been described as a function of peripheral chemosensors, multiple brainstem areas, including those with CPG function, are oxygen responsive in the range typical to peripheral chemosensor cells.

Peripheral chemoreceptors are located in carotid bodies just above the bifurcation of the common carotid and external carotid arteries, and in the aortic bodies above and below the aortic arch; the carotid bodies are the most important in humans. The most important variable in determining the activity of the carotid bodies is changes in Pao_2 and much of their afferent output result from changes in membrane potential due to oxygen sensitive potassium channels. Although the carotid bodies have a relatively high metabolic rate, they receive a very high flow for their rather small size. In the setting of normal oxygen delivery, the dissolved oxygen reflected by Pao_2 is sufficient for their metabolism. Stimulation of carotid bodies resulting in increased ventilation occurs when their oxygen supply is decreased below their metabolic requirements. This occurs when there is decreased Pao_2, decreased blood flow (low cardiac output), and impaired oxygen use (cyanide poisoning). Anemia and dyshemoglobinemias do not stimulate carotid body activation unless Pao_2 and the cardiac output are compromised. The relationship of Pao_2 and the stimulation of carotid bodies is nonlinear (Fig. 373-13).

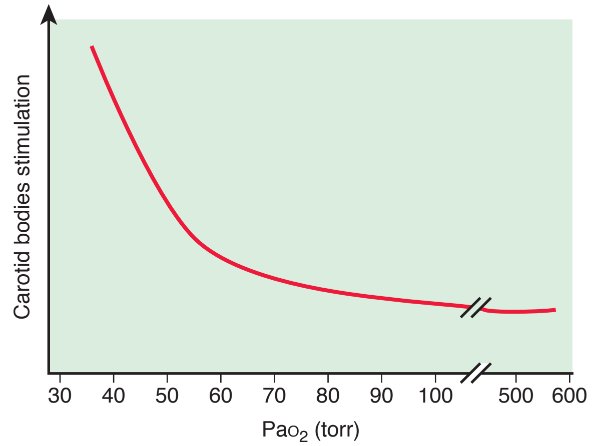

Figure 373-13 Significant stimulation of carotid bodies occurs with PaO_2 level <100 torr. A subjective feeling of dyspnea does not occur, however, until PaO_2 is <50 torr, at which point stimulation of the carotid bodies increases exponentially.

Carotid bodies are activated at a Pao_2 of <500 torr and are responsible for roughly a third of the respiratory drive during normal breathing. Their contribution to respiratory drive increases with decreasing age and may be the major determinant to respiratory drive in premature infants. Periodic breathing and other unstable respiratory patterns seen in newborns may be a result of an increased reliance of peripheral oxygen sensing in maintaining respiratory drive. As Pao_2 decreases, carotid body afferent output increases. A relatively small increase in ventilation occurs until the Pao_2 reaches 100 torr. Where the Pao_2 is <100 torr, the carotid body stimulation increases significantly. The carotid body receptor response rate is fast enough to alter their discharge rate during the respiratory cycle as a result of small cyclic changes in Pao_2 during inspiration and expiration. At Pao_2 levels <50 torr, carotid body stimulation increases exponentially. The most important effect of carotid body stimulation is an increase in respiratory rate and V_T. Additional effects include vasoconstriction, bradycardia, systemic hypertension, release of antidiuretic hormone, and stimulation of the adrenal medulla and adrenal cortex. The bradycardic effect of carotid body stimulation is overshadowed by the pulmonary reflex, which is induced by lung inflation and results in tachycardia. Patients in whom lung inflation is prevented are more likely to develop bradycardia after hypoxic stimulation of carotid bodies. Examples of such situations are fetal hypoxia, CNS depression, neuromuscular blockade, myopathy, neuropathy, and controlled ventilation. The peripheral chemoreceptors are responsible for almost all of the increase in ventilation that occurs in response to hypoxemia.

Peripheral chemoreceptors are also stimulated by an increase in $Paco_2$; this response requires a relatively large change in $Paco_2$ and results in a smaller rise in minute ventilation compared to the effect of CO_2 on central chemoreceptors. The peripheral chemoreceptors respond much more quickly (within 1 sec), however, whereas the central chemoreceptors can take minutes to respond. Thus peripheral chemoreceptors are important in the immediate rise in ventilation in response to a large and abrupt increase in $Paco_2$. Decreased pH also stimulates the peripheral chemoreceptors. The effect of pH is regardless of whether the acidosis is a result of respiratory or metabolic causes. Decreased Pao_2, increased $Paco_2$, and decreased pH act synergistically on carotid bodies. The combined effect is greater than the sum of their individual actions.

In contrast to the central chemoreceptors, the peripheral chemoreceptors are not easily depressed, such as by anesthesia or opiates. They also do not adapt easily to a persistent stimulus such as hypoxia, as do the central chemoreceptors to hypercarbia. The central chemoreceptors in hypoxic patients are relatively unresponsive to CO_2 at a time when respirations are predominantly stimulated by effects of hypoxia on peripheral chemoreceptors.

LUNG RECEPTORS

Stretch receptors are located within the airway smooth muscle. They are stimulated by lung inflation, and the impulse is conducted via the vagus nerve. The main effect of these receptors is to decrease the respiratory rate due to an inhibition of inspiratory muscle activity and an increase in exhalation time. This reflex is termed **Hering-Breuer inflation reflex**. Hering-Breuer deflation reflex stimulates inspiratory muscle activity in response to deflation of the lung. These reflexes are not operative during normal breathing in adults but may be important in newborns. Stretch receptors play an important role in minimizing the energy required for the WOB in respiratory disease. In diseases in which airway resistance is increased (asthma), more energy is needed to overcome airway resistance. Slow and deep breathing is most economical in such a situation because of relatively lower flow rate, and greater alveolar inflation is possible without stretching of the airway smooth muscle earlier during inspiration. In diseases of compliance (pulmonary edema), rapid and shallow breathing is most economical to keep the elastic work at minimum. Because of the stiffer alveoli in such situations, the transpulmonary pressure is transmitted to the airway smooth muscle earlier during inspiration, stimulating the stretch receptors and turning off inspiration.

Irritant receptors are present in between the epithelial cells in the airway mucous membrane. They are stimulated by particulate matter, noxious gases, and chemical fumes in the inspired gas, and also by cold air. The vagus nerve is responsible for conducting the impulse. Stimulation of irritant receptors results in bronchoconstriction and hyperpnea.

J receptors derive their name because of their juxtacapillary location. They lie in the alveolar walls close to the pulmonary capillaries. Pulmonary capillary engorgement and interstitial and alveolar wall edema provide stimuli for activation of the J receptors, resulting in shallow and rapid respirations and dyspnea. This is seen in left heart failure, ARDS, and interstitial diseases.

Muscle receptors important for regulation of respirations are those in the diaphragm and the intercostals. Stretch of the muscle sensed by the muscle spindle is used to control the strength of contraction. Excessive distortion of the diaphragm and the intercostals inhibits inspiratory activity when large negative intrathoracic pressure is required to move air, such as in airway obstruction. The soft chest walls of newborns and young infants are more susceptible to distortion; such children might respond to upper airway obstruction by premature cessation of inspiration and apnea rather than by the prolongation of inspiration required to move sufficient air past the obstruction.

Arterial baroreceptors located in aortic arch and carotid sinuses can influence respiration depending on arterial blood pressure. A decrease in blood pressure results in hyperventilation and an increased blood pressure causes hypoventilation.

Pain and temperature receptors also influence respirations, and they are especially pronounced in the neonates and young infants. A painful stimulus causes breath holding followed by hyperventilation. Increased skin temperature causes hyperventilation, and hypothermia results in hypoventilation. In the context of cold stimulus, the facial area is most important in causing apnea.

EFFECTORS

The most important effectors of respiration are the diaphragm, intercostals, and abdominal muscles. They receive impulses from the controller and effect ventilation. Accessory effectors such as sternocleidomastoids and paraspinal muscles may be called on to make additional contribution to the respiratory efforts in times of need. The effectors can be seriously impaired in malnutrition, spinal injury, and neuromuscular disease.

SLEEP STATES

Respiratory regulation is considerably affected by sleep. Sleep, in general, decreases central chemosensitivity to CO_2. $Paco_2$ is increased by a few torr compared to that in the wakeful state. Two broad categories of sleep states exist: *non–rapid eye movement* (NREM) and **REM**

sleep (see Chapter 19). NREM sleep is characterized by high-voltage, slow waves on electroencephalogram and is associated with fragmented mental activity. Muscle tone and movements are relatively unaffected. NREM sleep is likened to a "relatively inactive brain in a movable body." REM sleep is so termed because of the presence of episodic bursts of REMs.

The most clinically significant aspect of REM sleep is marked suppression of postural muscle tone and lack of spontaneous movements. REM sleep is likened to "a highly activated brain in a paralyzed body." Descending axons from the dorsal pontine tegmentum region are responsible for the REM sleep–specific characteristic atonia and paralysis. The predominant sleep pattern in premature babies is REM sleep. A full-term newborn has 50% REM sleep. Most of the sleep maturation occurs in the 1st 6 mo of life. Older children and adults spend approximately 20% of their sleep in the REM state. Sleep-related respiratory abnormalities are encountered predominantly in REM sleep.

Depression of muscle tone during REM sleep has 2 major effects. The relaxed and therefore increasingly compliant chest wall retracts inward much more during inspiration than a less-compliant chest wall would, resulting in an impediment to air inflow and a paradoxical (seesaw) pattern of breathing in which the abdomen and the chest wall move asynchronously. The second effect is that of relaxation of the genioglossus, palatal, and other upper airway muscles, causing airway obstruction. REM sleep–related respiratory abnormalities are commonly encountered in premature infants and in children with coexistent anatomic upper airway obstruction, obesity, and neuromuscular dysfunction.

REGULATION OF RESPIRATION IN SPECIAL SITUATIONS

Fetus, Newborns, and Young Infants

At various stages of development, the response to chemoreceptor and mechanoreceptor stimulation and the efficiency of effectors are markedly different. Unlike adults, who show an immediate and sustained response to hypoxemia characterized by hyperventilation, the newborn exhibits a biphasic response. After an initial brief period (1-2 min) of hyperventilation, the neonate and young infant develop hypoventilation and apnea when hypoxemia is sustained. This explains why such infants are much more prone to develop respiratory arrest in hypoxic states than are older children and adults. Lower gestational age of the infant is associated with a more pronounced and earlier apneic response to hypoxemia. Fetal respiratory activity, for example, is switched off when faced with oxygen deprivation. Maturation of carotid chemoreceptors may be an explanation for the differences in hypoxic response at various stages of development. Sensitivity of CO_2 sensors also undergoes maturation. Compared to adults and older children, neonates and young infants have decreased CO_2 responsiveness, as measured by an increase in minute alveolar ventilation for a given increase in $Paco_2$. Theophylline and caffeine increase the central chemoreceptor ventilatory response to CO_2 and decrease the number of apneic spells in premature babies.

The neonatal respiratory muscles are poorly equipped to sustain large workloads; they are more easily fatigued than in older children, and this significantly limits their ability to maintain adequate ventilation in lung disease. Also, the excessive inward retraction of the relatively soft infantile chest wall stimulates the intercostal muscles' stretch receptors, sending inhibitory impulses to the respiratory center. Young infants are therefore at greater risk of developing apnea when respiratory muscles are subjected to large elastic loads, such as in upper airway obstruction.

Many neurotransmitters involved in regulation of respiration also undergo developmental maturational changes. Serotoninergic neurons located in the raphe nuclei possess chemosensitive properties and respond to a decrease in pH. An increase in population of these neurons is associated with increasing chemosensitivity in the developing animal. Abnormalities of the arcuate nucleus, the human equivalent of the rat and cat medullary raphe, have been demonstrated at autopsy on infants dying of sudden infant death syndrome (SIDS; Chapter 375). Cohort studies of Japanese, African-American, and white victims of SIDS have implicated a homozygous gene that encodes for the long allele of the serotonin transporter promoter. SIDS victims are more likely to express the long allele of the serotonin transporter promoter and miss the short allele compared to controls. The delay in development of serotoninergic neurons or overexpression of the long allele for serotonin transporter promoter might explain the abnormal respiratory response to adverse conditions, which results in SIDS. Central chemoreception is also severely impaired in congenital central hypoventilation syndrome (**CCHS**), also known as Ondine's curse, which results in sleep-associated respiratory arrests. Mutations of *PHOX2B* gene located on chromosome 4 cause CCHS.

Chronic Hypoxia and Hypercarbia

The respiratory control mechanism is altered when exposed to chronic conditions. In patients with chronic pulmonary insufficiency with elevated $Paco_2$, the CSF pH has been normalized and the central chemoreceptors become unresponsive to CO_2. Renal compensation results in bicarbonate retention and relative normalization of blood pH. Arterial hypoxemia remains the chief stimulus for ventilation, which is predominantly dependent on peripheral chemoreceptor stimulation by a low Pao_2. Administration of a high amount of oxygen in such patients carries a risk of sudden removal of the hypoxic stimulus, cessation of breathing, exacerbation of hypercarbia and CO_2 narcosis, and coma. Patients with chronic obstructive pulmonary disease and neuromuscular disease are especially susceptible to this complication. Children with bronchopulmonary dysplasia or with muscular dystrophy who have had a high $Paco_2$, with or without supplemental oxygen, can develop serious hypoventilation and respiratory acidosis when their Pao_2 is increased more than their baseline with administration of a higher amount of oxygen.

Chronically hypoxic patients, such as those living at high altitude and those with cyanotic heart disease and interstitial lung disease, have a blunted chemoreceptor function and poor response to further hypoxemia. It is of interest to the clinician that children with poorly controlled asthma also show a blunted hypoxic response and can appear to be breathing relatively comfortably in spite of dangerously low Pao_2. Such children and their caretakers are at risk of failing to appreciate the severity of their disease, which can result in delay in instituting appropriate therapy.

Chapter 374

Diagnostic Approach to Respiratory Disease

Gabriel G. Haddad and Thomas P. Green

A careful history and physical examination are essential to the accurate diagnosis of a child presenting with respiratory signs and/or symptoms. Sometimes, but not always, additional diagnostic tests and modalities are required.

HISTORY

The history begins with a narrative provided by the parent/caretaker with input from the patient. The history should include questions about respiratory symptoms (dyspnea, cough, pain, wheezing, snoring, apnea, cyanosis), chronicity, timing during day or night, and associations with activities including exercise or food intake. The respiratory system interacts with a number of other systems, and questions related

to cardiac, gastrointestinal, central nervous, hematologic, and immune systems may be relevant. Questions related to gastrointestinal reflux, congenital abnormalities (airway anomalies, ciliary dyskinesia), or immune status may be important in a patient with repeated pneumonia. The family history is essential and should include inquiries about siblings and other close relatives with similar symptoms or any chronic disease with respiratory components.

PHYSICAL EXAMINATION

Respiratory dysfunction usually produces detectable alterations in the pattern of breathing. Values for normal respiratory rates are presented in Table 67-1 (in Chapter 67) and depend on many factors, most importantly, age. Repeated respiratory rate measurements are necessary because respiratory rates, especially in the young, are exquisitely sensitive to extraneous stimuli. Sleeping respiratory rates are more reproducible in infants than those obtained during feeding or activity. These rates vary among infants but average 40-50 breaths/min in the 1st few wk of life and usually <60 breaths/min in the 1st few days of life.

Respiratory control abnormalities can cause the child to breathe at a low rate or periodically. Mechanical abnormalities produce compensatory changes that are generally directed at altering minute ventilation to maintain alveolar ventilation. Decreases in lung compliance require increases in muscular force and breathing rate, leading to variable increases in chest wall retractions and nasal flaring. The respiratory excursions of children with restrictive disease are shallow. An expiratory grunt is common as the child attempts to raise the *functional residual capacity* **(FRC)** by closing the glottis at the end of expiration. Children with obstructive disease might take slower, deeper breaths (see Chapter 373). When the obstruction is **extrathoracic** (from the nose to the mid-trachea), inspiration is more prolonged than expiration, and an inspiratory stridor can usually be heard (see Fig. 373-8 in Chapter 373). When the obstruction is **intrathoracic,** expiration is more prolonged than inspiration, and the patient often has to make use of accessory expiratory muscles. Intrathoracic obstruction results in air trapping and, therefore, a larger residual volume and, perhaps, greater FRC (see Fig. 373-10 in Chapter 373).

Lung percussion has limited value in small infants because it cannot discriminate between noises originating from tissues that are close to each other. In adolescents and adults, percussion is usually dull in restrictive lung disease, with a pleural effusion, pneumonia, and atelectasis, but it is tympanitic in obstructive disease (asthma, pneumothorax).

Auscultation confirms the presence of inspiratory or expiratory prolongation and provides information about the symmetry and quality of air movement. In addition, it often detects abnormal or adventitious sounds such as **stridor** (a predominant inspiratory monophonic noise), **crackles** (or **rales**) (high-pitched, interrupted sounds found during inspiration and more rarely during early expiration, which denote opening of previously closed air spaces), or **wheezes** (musical, continuous sounds usually caused by the development of turbulent flow in narrow airways) (Table 374-1). **Digital clubbing** is a sign of chronic hypoxia and chronic lung disease (Fig. 374-1) but may be a result of nonpulmonary etiologies (Table 374-2).

Table 374-1 Lung Sound Nomenclature

TYPE	SOUND
DISCONTINUOUS	
Fine (high pitch, low amplitude, short duration)	Fine crackles/rales
Coarse (low pitch, high amplitude, long duration)	Coarse crackles
CONTINUOUS	
High pitch	Wheezes
Low pitch	Rhonchi

BLOOD GAS ANALYSIS

See also Chapters 373.7 and 373.8.

An arterial blood gas analysis is probably the single most useful rapid test of pulmonary function. Although this analysis does not specify the cause of the condition or the specific nature of the disease process, it can give an overall assessment of the functional state of the respiratory system and clues about the pathogenesis of the disease. Because the detection of cyanosis is influenced by skin color, perfusion, and blood hemoglobin concentration, the clinical detection by inspection is an unreliable sign of hypoxemia. Arterial hypertension, tachycardia, and diaphoresis are late, and not exclusive, signs of hypoventilation.

Blood gas exchange is evaluated most accurately by the direct measurement of arterial pressure of oxygen (Po_2), pressure of carbon dioxide (Pco_2), and pH. The blood specimen is best collected anaerobically in a heparinized syringe containing only enough heparin solution to displace the air from the syringe. The syringe should be sealed, placed in ice, and analyzed immediately. Although these measurements have no substitute in many conditions, they require arterial puncture and have been replaced to a great extent by noninvasive monitoring, such as capillary samples and/or oxygen saturation.

The age and clinical condition of the patient need to be taken into account when interpreting blood gas tensions. With the exception of neonates, values of arterial Po_2 <85 mm Hg are usually abnormal for a child breathing room air at sea level. Calculation of the alveolar–arterial oxygen gradient is useful in the analysis of arterial oxygenation, particularly when the patient is not breathing room air or in the presence of hypercarbia. Values of arterial Pco_2 >45 mm Hg usually indicate hypoventilation or a severe ventilation–perfusion mismatch, unless they reflect respiratory compensation for metabolic alkalosis (see Chapter 55).

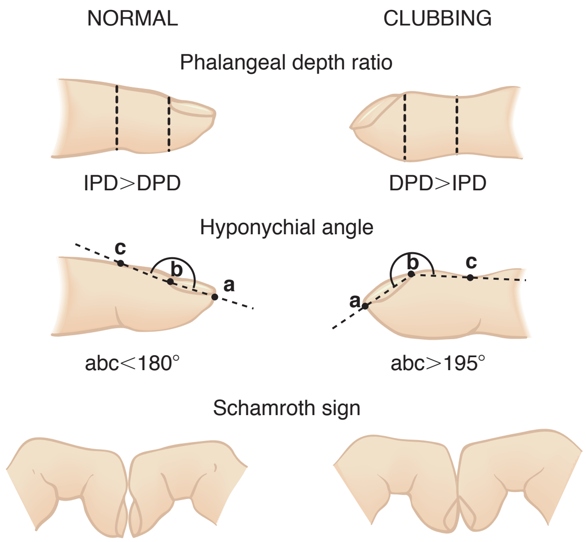

Figure 374-1 Finger clubbing can be measured in different ways. The ratio of the distal phalangeal diameter (DPD) over the interphalangeal diameter (IPD), or the phalangeal depth ratio, is <1 in normal subjects but increases to >1 with finger clubbing. The DPD/IPD can be measured with calipers or, more accurately, with finger casts. The hyponychial angle can be measured from lateral projections of the finger contour on a magnifying screen and is usually <180 degrees in normal subjects but >195 degrees in patients with finger clubbing. For bedside clinical assessment, the Schamroth sign is useful. The dorsal surfaces of the terminal phalanges of similar fingers are placed together. With clubbing, the normal diamond-shaped aperture or "window" at the bases of the nail beds disappears, and a prominent distal angle forms between the ends of the nails. In normal subjects, this angle is minimal or nonexistent. *(From Pasterkamp H: The history and physical examination. In Wilmott RW, Boat TF, Bush A, et al, editors:* Kendig and Chernick's disorders of the respiratory tract in children, *ed 8, Philadelphia, 2012, Elsevier.)*

TRANSILLUMINATION OF THE CHEST

In infants up to at least 6 mo of age, a pneumothorax (see Chapter 101.12) can often be diagnosed by transilluminating the chest wall using a fiberoptic light probe. Free air in the pleural space often results in an unusually large halo of light in the skin surrounding the probe. Comparison with the contralateral chest is often very helpful in interpreting findings. This test is unreliable in older patients and in those with subcutaneous emphysema or atelectasis.

RADIOGRAPHIC TECHNIQUES

Chest X-Rays

A posteroanterior and a lateral view (upright and in full inspiration) should be obtained except in situations in which the child is medically unstable. Portable films, although useful in the latter situation, can give a somewhat distorted image. Expiratory films can be misinterpreted, although a comparison of expiratory and inspiratory films may be useful in evaluating a child with suspected foreign body (localized failure of the lung to empty reflects bronchial obstruction: Chapter 387). If pleural fluid is suspected (see Chapter 410), decubitus films are indicated. Films taken in a recumbent position are difficult to interpret if there is fluid within the pleural space or a cavity.

Upper Airway Film

A lateral view of the neck can yield invaluable information about upper airway obstruction (see Chapter 385) and particularly about the condition of the retropharyngeal, supraglottic, and subglottic spaces (which should also be viewed in an anteroposterior projection). Knowing the phase of respiration during which the film was taken is often essential for accurate interpretation. Magnified airway films are often helpful in delineating the upper airways. Patients with suggested obstruction should not be unattended in the radiology department.

Sinus and Nasal Films

The general utility of roentgenographic examination of the sinuses is uncertain because of the large number of films with positive findings (low sensitivity and specificity). Imaging studies are not necessary to confirm the diagnosis of sinusitis in children younger than age 6 yr. CT scans are indicated if surgery is required, in cases of complications caused by sinus infection, in immunodeficient patients, and for recurrent infections that are not responsive to medical management.

Chest Computed Tomography and Magnetic Resonance Imaging

Chest CT and MRI can potentially provide images of higher quality and sensitivity than is possible with other imaging modalities. For example, chest CT identifies early abnormalities in young children with cystic fibrosis before pathologic changes are detectable by either plain chest radiographs or pulmonary function testing. Several caveats, however, must be noted. Conventional chest CT involves considerably higher radiation doses than plain films (see Chapter 718). The time required to perform chest CT examinations and the complications of respiratory and body motion mandates the use of sedation for this procedure in many infants and young children. However, improvements in imaging hardware and software have drastically reduced required radiation doses as well as imaging time, obviating the need for sedation in many patients. Chest CT is particularly useful in evaluating very small lesions (e.g., early metastases, mediastinal and pleural lesions, solid or cystic parenchymal lesions, pulmonary embolism, and bronchiectasis). The use of intravenous contrast material during CT imaging enhances vascular structures, distinguishing vessels from other soft-tissue densities. MRI does not involve ionizing radiation, but long imaging times are still involved, and sedation will be necessary to limit spontaneous movement. The utility of MRI of the chest is largely limited to the analysis of mediastinal, hilar, and vascular anatomy. Parenchymal structures and lesions are not well evaluated by MRI.

Fluoroscopy

Fluoroscopy is especially useful for evaluating stridor and abnormal movement of the diaphragm or mediastinum. Many procedures, such as needle aspiration or biopsy of a peripheral lesion, are also best accomplished with the aid of fluoroscopy, CT, or ultrasonography. Videotape recording, which does not increase radiation exposure, can allow detailed study through replay capability during a brief exposure to fluoroscopy.

Barium Swallow

A barium swallow study, performed with fluoroscopy and spot films, is indicated in the evaluation of patients with recurrent pneumonia, persistent cough of undetermined cause, stridor, or persistent wheezing. The technique can be modified by using barium of different textures and thicknesses, ranging from thin liquid to solids, to evaluate swallowing mechanics, the presence of vascular rings (see Chapter 386), and tracheoesophageal fistulas (see Chapter 319), especially when aspiration is suspected. A contrast esophagram has been used in evaluating newborns with suggested esophageal atresia, but this procedure entails a high risk of pulmonary aspiration and is not usually recommended. Barium swallows are useful in evaluating suggested gastroesophageal reflux (see Chapter 323), but because of the high incidence of asymptomatic reflux in infants, the applicability of the findings to the clinical problem may be complicated.

Pulmonary Arteriography and Aortograms

Pulmonary arteriography has been used to allow detailed evaluation of the pulmonary vasculature; has been helpful in assessing pulmonary blood flow and in diagnosing congenital anomalies, such as lobar agenesis, unilateral hyperlucent lung, vascular rings, and arteriovenous malformations; and it is sometimes useful in evaluating solid or cystic

lesions. Thoracic aortograms demonstrate the aortic arch, its major vessels, and the systemic (bronchial) pulmonary circulation. They are useful in evaluating vascular rings and suspected pulmonary sequestration. Although most hemoptysis is from the bronchial arteries, bronchial arteriography is seldom helpful in diagnosing or treating intrapulmonary bleeding in children. Real-time and Doppler echocardiography and thoracic CT with contrast are noninvasive methods that often reveal similar information and should be considered before arteriography is performed.

Radionuclide Lung Scans

The usual scan uses intravenous injection of material (macroaggregated human serum albumin labeled with ^{99m}Tc) that will be trapped in the pulmonary capillary bed. The distribution of radioactivity, proportional to pulmonary capillary blood flow, is useful in evaluating pulmonary embolism and congenital cardiovascular and pulmonary defects. Acute changes in the distribution of pulmonary perfusion can reflect alterations of pulmonary ventilation.

The distribution of pulmonary ventilation can also be determined by scanning after the patient inhales a radioactive gas such as xenon-133. After the intravenous injection of xenon-133 dissolved in saline, pulmonary perfusion and ventilation can be evaluated by continuous recording of the rate of appearance and disappearance of the xenon over the lung. Appearance of xenon early after injection is a measure of perfusion, and the rate of washout during breathing is a measure of ventilation in the pediatric population. The most important indication for this test is to demonstrate defects in the pulmonary arterial distribution that can occur with congenital malformations or pulmonary embolism. **Spiral reconstruction CT** with contrast medium enhancement is very helpful in evaluating pulmonary thrombi and emboli. Abnormalities in regional ventilation are also easily demonstrable in congenital lobar emphysema, cystic fibrosis, and asthma.

PULMONARY FUNCTION TESTING

See also Chapters 373.7 and 373.9.

The measurement of respiratory function in infants and young children can be difficult because of the lack of cooperation. Attempts have been made to overcome this limitation by creating standard tests that do not require the patient's active participation. Respiratory function tests still provide only a partial insight into the mechanisms of respiratory disease at early ages.

Whether restrictive or obstructive, most forms of respiratory disease cause alterations in lung volume and its subdivisions. Restrictive diseases typically decrease **total lung capacity (TLC).** TLC includes residual volume, which is not accessible to direct determinations. It must therefore be measured indirectly by gas dilution methods or, preferably, by **plethysmography.** Restrictive disease also decreases **vital capacity (VC).** Obstructive diseases produce gas trapping and thus increase residual volume and FRC, particularly when these measurements are considered with respect to TLC.

Airway obstruction is most commonly evaluated from determinations of gas flow in the course of a forced expiratory maneuver. The **peak expiratory flow** is reduced in advanced obstructive disease. The wide availability of simple devices that perform this measurement at the bedside makes it useful for assessing children who have airway obstruction. Evaluation of peak flows requires a voluntary effort, and peak flows may not be altered when the obstruction is moderate or mild. Other gas flow measurements require that the child inhale to TLC and then exhale as far and as fast as possible for several seconds. Cooperation and good muscle strength are therefore necessary for the measurements to be reproducible. The **forced expiratory volume in 1 sec** (FEV_1) correlates well with the severity of obstructive diseases. The **maximal midexpiratory flow rate,** the average flow during the middle 50% of the forced VC, is a more reliable indicator of mild airway obstruction. Its sensitivity to changes in residual volume and VC, however, limits its use in children with more severe disease. The construction of flow-volume relationships during the forced VC maneuvers overcomes some of these limitations by expressing the expiratory flows as a function of lung volume.

A **spirometer** is used to measure VC and its subdivisions and expiratory (or inspiratory) flow rates (see Fig. 365-1 in Chapter 365). A simple manometer can measure the maximal inspiratory and expiratory force a subject generates, normally at least 30 cm H_2O, which is useful in evaluating the neuromuscular component of ventilation. Expected normal values for VC, FRC, TLC, and residual volume are obtained from prediction equations based on body height.

Flow rates measured by spirometry usually include the FEV_1 and the **maximal midexpiratory flow rate.** More information results from a maximal expiratory flow-volume curve, in which expiratory flow rate is plotted against expired lung volume (expressed in terms of either VC or TLC). Flow rates at lung volumes less than approximately 75% VC are relatively independent of effort. Expiratory flow rates at low lung volumes (<50% VC) are influenced much more by small airways than are flow rates at high lung volumes (FEV_1). The flow rate at 25% VC is a useful index of small airway function. Low flow rates at high lung volumes associated with normal flow at low lung volumes suggest upper airway obstruction.

Airway resistance (R_{AW}) is measured in a plethysmograph, or, alternatively, the reciprocal of R_{AW}, **airway conductance**, may be used. Because R_{AW} measurements vary with the lung volume at which they are taken, it is convenient to use **specific airway resistance,** SR_{AW} ($SR_{AW} = R_{AW}$/lung volume), which is nearly constant in subjects older than age 6 yr (normally <7 sec/cm H_2O).

The **diffusing capacity for carbon monoxide** is related to oxygen diffusion and is measured by rebreathing from a container having a known initial concentration of carbon monoxide or by using a single-breath technique. Decreases in diffusing capacity for carbon monoxide reflect decreases in effective alveolar capillary surface area or decreases in diffusibility of the gas across the alveolar-capillary membrane. Primary diffusion abnormalities are unusual in children; therefore, this test is most commonly employed in children with rheumatologic or autoimmune diseases and in children exposed to toxic drugs to the lungs (e.g., oncology patients) or chest wall radiation. Regional gas exchange can be conveniently estimated with the perfusion-ventilation xenon scan. Determining arterial blood gas levels also discloses the effectiveness of alveolar gas exchange.

Pulmonary function testing, although rarely resulting in a diagnosis, is helpful in defining the type of process (obstruction, restriction) and the degree of functional impairment, in following the course and treatment of disease, and in estimating the prognosis. It is also useful in preoperative evaluation and in confirmation of functional impairment in patients having subjective complaints but a normal physical examination. In most patients with obstructive disease, a repeat test after administering a bronchodilator is warranted.

Most tests require some cooperation and understanding by the patient, and interpretation is greatly facilitated if the test conditions and the patient's behavior during the test are known. Infants and young children who cannot or will not cooperate with test procedures can be studied in a limited number of ways, which often require sedation. Flow rates and pressures during tidal breathing, with or without transient interruption of the flow, may be useful to assess some aspects of R_{AW} or obstruction and to measure compliance of the lungs and thorax. Expiratory flow rates can be studied in sedated infants with passive compression of the chest and abdomen with a rapidly inflatable jacket. Gas dilution or plethysmographic methods can also be used in sedated infants to measure FRC and R_{AW}.

MICROBIOLOGY: EXAMINATION OF LUNG SECRETIONS

The specific diagnosis of infection in the lower respiratory tract depends on the proper handling of an adequate specimen obtained in an appropriate fashion. Nasopharyngeal or throat cultures are often used but might not correlate with cultures obtained by more-direct techniques from the lower airways. Sputum specimens are preferred and are often obtained from patients who do not expectorate by deep throat swab immediately after coughing or by saline nebulization. Specimens can also be obtained directly from the tracheobronchial tree by nasotracheal aspiration (usually heavily contaminated), by

transtracheal aspiration through the cricothyroid membrane (useful in adults and adolescents but hazardous in children), and in infants and children by a sterile catheter inserted into the trachea either during direct laryngoscopy or through a freshly inserted endotracheal tube. A specimen can also be obtained at bronchoscopy. A percutaneous lung tap or an open biopsy is the only way to obtain a specimen absolutely free of oral flora.

A specimen obtained by direct expectoration is usually assumed to be of tracheobronchial origin, but often, especially in children, it is not from this source. The presence of alveolar macrophages (large mononuclear cells) is the hallmark of tracheobronchial secretions. Nasopharyngeal and tracheobronchial secretions can contain ciliated epithelial cells, which are more commonly found in sputum. Nasopharyngeal and oral secretions often contain large numbers of squamous epithelial cells. Sputum can contain both ciliated and squamous epithelial cells.

During sleep, mucociliary transport continually brings tracheobronchial secretions to the pharynx, where they are swallowed. An early-morning fasting gastric aspirate often contains material from the tracheobronchial tract that is suitable for culture for acid-fast bacilli.

The absence of polymorphonuclear leukocytes in a Wright-stained smear of sputum or **bronchoalveolar lavage** (BAL) fluid containing adequate numbers of macrophages may be significant evidence against a bacterial infectious process in the lower respiratory tract, assuming that the patient has normal neutrophil counts and function. Eosinophils suggest allergic disease. Iron stains can reveal hemosiderin granules within macrophages, suggesting pulmonary hemosiderosis. Specimens should also be examined by Gram stain. Bacteria within or near macrophages and neutrophils can be significant. Viral pneumonia may be accompanied by intranuclear or cytoplasmic inclusion bodies visible on Wright-stained smears, and fungal forms may be identifiable on Gram or silver stains.

With advances in the area of genomics and the speed with which it is possible to identify microbes, microbiologic analysis has been expanded. For example, specific bacteria in the lungs of children with cystic fibrosis (see Chapter 403) are linked to morbidity and mortality. There is a correlation between patient age and morbidity and mortality (as expected) but that there are important microbes that are correlated either negatively or positively with early or late pathogenic processes. *Haemophilus influenzae* (see Chapter 194) is negatively correlated and *Pseudomonas aeruginosa* and *Stenotrophomonas maltophilia* (see Chapter 205) have a strong positive correlation with patient age in cystic fibrosis. The microbiota diversity is much broader in those who are healthier individuals or those that are younger patients with cystic fibrosis than the older and sicker population.

In addition, the microbiomes (see Chapter 171) in the respiratory tract of smokers and nonsmokers differ substantially. In all patients, most of the bacteria found in the lungs are also present in the oral cavity, as expected, although some bacteria, such as *Haemophilus* and enterobacteria are much more represented in the lungs than in the mouth. Principal differences between smokers and nonsmokers are found in the microbiome in the mouth, for example, bacteria like *Neisseria*.

EXERCISE TESTING

Exercise testing (see Chapter 423.5) is a more-direct approach for detecting diffusion impairment as well as other forms of respiratory disease. Exercise is a strong provocateur of bronchospasm in susceptible patients, so exercise testing can be useful in the diagnosis of patients with asthma that is only apparent with activity. Measurements of heart and respiratory rate, minute ventilation, oxygen consumption, carbon dioxide production, and arterial blood gases during incremental exercise loads often provide invaluable information about the functional nature of the disease. Often a simple assessment of the patient's exercise tolerance in conjunction with other, more static forms of respiratory function testing can allow a distinction between respiratory and nonrespiratory disease in children.

SLEEP STUDIES

See Chapter 19.

AIRWAY VISUALIZATION AND LUNG SPECIMEN–BASED DIAGNOSTIC TESTS

Laryngoscopy

The evaluation of stridor, problems with vocalization, and other upper airway abnormalities usually requires direct inspection. Although indirect (mirror) laryngoscopy may be reasonable in older children and adults, it is rarely feasible in infants and small children. Direct laryngoscopy may be performed with either a rigid or a flexible instrument. The safe use of the rigid scope for examining the upper airway requires topical anesthesia and either sedation or general anesthesia, whereas the flexible laryngoscope can often be used in the office setting with or without sedation. Further advantages to the flexible scope include the ability to assess the airway without the distortion that may be introduced by the use of the rigid scope and the ability to assess airway dynamics more accurately. Because there is a relatively high incidence of concomitant lesions in the upper and lower airways, it is often prudent to examine the airways above and below the glottis, even when the primary indication is in the upper airway (stridor).

Bronchoscopy and Bronchoalveolar Lavage

Bronchoscopy is the inspection of the airways. BAL is a method used to obtain a representative specimen of fluid and secretions from the lower respiratory tract, which is useful for the cytologic and microbiologic diagnosis of lung diseases, especially in those who are unable to expectorate sputum. BAL is performed after the general inspection of the airways and before tissue sampling with a brush or biopsy forceps. BAL is accomplished by gently wedging the scope into a lobar, segmental, or subsegmental bronchus and sequentially instilling and withdrawing sterile nonbacteriostatic saline in a volume sufficient to ensure that some of the aspirated fluid contains material that originated from the alveolar space. Nonbronchoscopic BAL can be performed, although with less accuracy and, therefore, less-reliable results, in intubated patients by instilling and withdrawing saline through a catheter passed though the artificial airway and blindly wedged into a distal airway. In either case, the presence of alveolar macrophages documents that an alveolar sample has been obtained. Because the methods used to perform BAL involve passage of the equipment through the upper airway, there is a risk of contamination of the specimen by upper airway secretions. Careful cytologic examination and quantitative microbiologic cultures are important for correct interpretation of the data. BAL can often obviate the need for more-invasive procedures such as open lung biopsy, especially in immunocompromised patients.

Indications for diagnostic bronchoscopy and BAL include recurrent or persistent pneumonia or atelectasis, unexplained or localized and persistent wheeze, the suspected presence of a foreign body, hemoptysis, suspected congenital anomalies, mass lesions, interstitial disease, and pneumonia in the immunocompromised host. Indications for therapeutic bronchoscopy and BAL include bronchial obstruction by mass lesions, foreign bodies or mucus plugs, and general bronchial toilet and bronchopulmonary lavage. The patient undergoing bronchoscopy ventilates around the flexible scope, whereas with the rigid scope, ventilation is accomplished through the scope. Rigid bronchoscopy is preferentially indicated for extracting foreign bodies, for removing tissue masses, and in patients with massive hemoptysis. In other cases, the flexible scope offers the advantages that it can be passed through endotracheal or tracheostomy tubes, can be introduced into bronchi that come off the airway at acute angles, and can be safely and effectively inserted with topical anesthesia and conscious sedation.

Regardless of the instrument used, the procedure performed, or its indications, the most common complications are related to sedation. The relatively more common complications related to the bronchoscopy itself include transient hypoxemia, laryngospasm, bronchospasm, and cardiac arrhythmias. Iatrogenic infection, bleeding, pneumothorax, and pneumomediastinum are rare but reported complications of bronchoscopy or BAL. Bronchoscopy in the setting of possible pulmonary abscess or hemoptysis must be undertaken with advance preparations for definitive airway control, mindful of the possibility that pus or blood might flood the airway. Subglottic edema is a more common complication of rigid bronchoscopy than of flexible procedures, in

which the scopes are smaller and less likely to traumatize the mucosa. Postbronchoscopy croup is treated with oxygen, mist, vasoconstrictor aerosols, and corticosteroids as necessary.

Thoracoscopy

The pleural cavity can be examined through a thoracoscope, which is similar to a rigid bronchoscope. The thoracoscope is inserted through an intercostal space and the lung is partially deflated, thus allowing the operator to view the surface of the lung, the pleural surface of the mediastinum and diaphragm, and the parietal pleura. Multiple thoracoscopic instruments can be inserted, allowing endoscopic biopsy of the lung or pleura, resection of blebs, abrasion of the pleura, and ligation of vascular rings.

Thoracentesis

For diagnostic or therapeutic purposes, fluid can be removed from the pleural space by needle. Generally, as much fluid as possible should be withdrawn, and an upright chest roentgenogram should be obtained after the procedure. Complications of thoracentesis include infection, pneumothorax, and bleeding. Thoracentesis on the right may be complicated by puncture or laceration of the capsule of the liver and, on the left, by puncture or laceration of the capsule of the spleen. Specimens obtained should always be cultured, examined microscopically for evidence of bacterial infection, and evaluated for total protein and total differential cell counts. Lactic acid dehydrogenase, glucose, cholesterol, triglyceride (chylous), and amylase determinations may also be useful. If malignancy is suspected, cytologic examination is imperative.

Transudates result from mechanical factors influencing the rate of formation or reabsorption of pleural fluid and generally require no further diagnostic evaluation. Exudates result from inflammation or other disease of the pleural surface and underlying lung and require a more complete diagnostic evaluation. In general, transudates have a total protein of <3 g/dL or a ratio of pleural protein to serum protein <0.5, a total leukocyte count of fewer than 2,000/mm^3 with a predominance of mononuclear cells, and low lactate dehydrogenase levels. Exudates have high protein levels and a predominance of polymorphonuclear cells (although malignant or tuberculous effusions can have a higher percentage of mononuclear cells). Complicated exudates often require continuous chest tube drainage and have a pH <7.2. Tuberculous effusions can have low glucose and high cholesterol content.

Lung Tap

Using a technique similar to that used for thoracentesis, a percutaneous lung tap is the most direct method of obtaining bacteriologic specimens from the pulmonary parenchyma and is the only technique other than open lung biopsy not associated with at least some risk of contamination by oral flora. After local anesthesia, a needle attached to a syringe containing nonbacteriostatic sterile saline is inserted using aseptic technique through the inferior aspect of an intercostal space in the area of interest. The needle is rapidly advanced into the lung; the saline is injected and reaspirated, and the needle is withdrawn. These actions are performed as quickly as possible. This procedure usually yields a few drops of fluid from the lung, which should be cultured and examined microscopically.

Major indications for a lung tap are infiltrates of undetermined cause, especially those unresponsive to therapy in immunosuppressed patients who are susceptible to unusual organisms. Complications are the same as for thoracentesis, but the incidence of pneumothorax is higher and somewhat dependent on the nature of the underlying disease process. In patients with poor pulmonary compliance, such as children with *Pneumocystis* pneumonia, the rate can approach 30%, with 5% requiring chest tubes. Bronchopulmonary lavage has replaced lung taps for most purposes.

Lung Biopsy

Lung biopsy may be the only way to establish a diagnosis, especially in protracted, noninfectious disease. In infants and small children, thoracoscopic or open surgical biopsies are the procedures of choice, and in expert hands, there is low morbidity. Biopsy through the 3.5 mm diameter pediatric bronchoscopes limits the sample size and diagnostic abilities. As well as ensuring that an adequate specimen is obtained, the surgeon can inspect the lung surface and choose the site of biopsy. In older children, transbronchial biopsies can be performed using flexible forceps through a bronchoscope, an endotracheal tube, a rigid bronchoscope, or an endotracheal tube, usually with fluoroscopic guidance. This technique is most appropriately used when the disease is diffuse, as in the case of *Pneumocystis* pneumonia, or after rejection of a transplanted lung. The diagnostic limitations related to the small size of the biopsy specimens can be mitigated by the ability to obtain several samples. The risk of pneumothorax related to bronchoscopy is increased when transbronchial biopsies are part of the procedure; however, the ability to obtain biopsy specimens in a procedure performed with topical anesthesia and conscious sedation offers advantages to the select population for whom this procedure offers a reasonable diagnostic yield.

Chapter 375

Sudden Infant Death Syndrome

Carl E. Hunt and Fern R. Hauck

Sudden infant death syndrome (SIDS) is defined as the sudden, unexpected death of an infant that is unexplained by a thorough postmortem examination, which includes a complete autopsy, investigation of the scene of death, and review of the medical history. An autopsy is essential to identify possible natural explanations for sudden unexpected death such as congenital anomalies or infection and to diagnose traumatic child abuse (Tables 375-1, 375-2, and 375-3; see Chapter 40). The autopsy typically cannot distinguish between SIDS and intentional suffocation, but the scene investigation and medical history may be of help if inconsistencies are evident. **Sudden unexpected infant death (SUID)** is a term that encompasses all sudden unexpected infant deaths. Unexplained SUID is equivalent to SIDS.

EPIDEMIOLOGY

SIDS is the third leading cause of infant mortality in the United States, accounting for approximately 8% of all infant deaths. It is the most common cause of postneonatal infant mortality, accounting for 40-50% of all deaths between 1 mo and 1 yr of age. The annual rate of SIDS in the United States was stable at 1.3-1.4 per 1,000 live births (approximately 7,000 infants/year) before 1992, when it was recommended that infants sleep nonprone as a way to reduce risk for SIDS. Since then, particularly after initiation of the national Back to Sleep campaign in 1994, the rate of SIDS progressively declined and then leveled off in 2001 at 0.55 per 1,000 live births (2,234 infants). The rates have remained stagnant since that time; in 2009 it was 0.54 per 1,000 live births (2,231 infants). The decline in the number of SIDS deaths in the United States and other countries has been attributed to increasing use of the supine position for sleep. In 1992, 82% of sampled infants in the United States were placed prone for sleep. Several other countries have decreased prone sleeping prevalence to ≤2%, but in the United States in 2009, 11% of infants were still being placed prone for sleep and 13% were being placed in the side position. Among black infants, these rates were even higher: 22% prone and 22% side in 2009.

Table 375-1 Differential Diagnosis of Sudden Unexpected Infant Death

CAUSE OF DEATH	PRIMARY DIAGNOSTIC CRITERIA	CONFOUNDING FACTOR(S)	FREQUENCY DISTRIBUTION (%)
EXPLAINED AT AUTOPSY			
Natural			18-20*
Infections	History, autopsy, and cultures	If minimal findings: SIDS	35-46†
Congenital anomaly	History and autopsy	If minimal findings: SIDS	14-24†
Unintentional injury	History, scene investigation, autopsy	Traumatic child abuse	15*
Traumatic child abuse	Autopsy and scene investigation	Unintentional injury	13-24*
Other natural causes	History and autopsy	If minimal findings: SIDS, or intentional suffocation	12-17*
UNEXPLAINED AT AUTOPSY			
SIDS	History, scene investigation, absence of explainable cause at autopsy	Intentional suffocation	80-82%
Intentional suffocation (filicide)	Perpetrator confession, absence of explainable cause at autopsy	SIDS	Unknown, but <5% of all SUID
Accidental suffocation or strangulation in bed (ASSB)	History and scene investigation, ideally including doll re-enactment	Assigned to ICD-10 code (SIDS) for U.S. vital statistics database Unexplained Undetermined	Varies with individual medical examiners and coroners

*As a percentage of all sudden unexpected infant deaths explained at autopsy.

†As a percentage of all natural causes of sudden unexpected infant deaths explained at autopsy.

ICD-10, International Classification of Diseases, Version 10; SIDS, sudden infant death syndrome; SUDI, sudden unexpected death in infancy.

Table 375-2 Conditions That Can Cause Apparent Life-Threatening Events or Sudden Unexpected Infant Death

CENTRAL NERVOUS SYSTEM
- Arteriovenous malformation
- Subdural hematoma
- Seizures
- Congenital central hypoventilation
- Neuromuscular disorders (Werdnig-Hoffmann disease)
- Chiari crisis
- Leigh syndrome

CARDIAC
- Subendocardial fibroelastosis
- Aortic stenosis
- Anomalous coronary artery
- Myocarditis
- Cardiomyopathy
- Arrhythmias (prolonged Q-T syndrome, Wolff-Parkinson-White syndrome, congenital heart block)

PULMONARY
- Pulmonary hypertension
- Vocal cord paralysis
- Aspiration
- Laryngotracheal disease

GASTROINTESTINAL
- Diarrhea and/or dehydration
- Gastroesophageal reflux
- Volvulus

ENDOCRINE–METABOLIC
- Congenital adrenal hyperplasia
- Malignant hyperpyrexia
- Long- or medium-chain acyl coenzyme A deficiency
- Hyperammonemias (urea cycle enzyme deficiencies)
- Glutaric aciduria
- Carnitine deficiency (systemic or secondary)
- Glycogen storage disease type I
- Maple syrup urine disease
- Congenital lactic acidosis
- Biotinidase deficiency

INFECTION
- Sepsis
- Meningitis
- Encephalitis
- Brain abscess
- Pyelonephritis
- Bronchiolitis (respiratory syncytial virus)
- Infant botulism
- Pertussis

TRAUMA
- Child abuse
- Accidental or intentional suffocation
- Physical trauma
- Factitious syndrome (formerly Munchausen syndrome) by proxy

POISONING (INTENTIONAL OR UNINTENTIONAL)
- Boric acid
- Carbon monoxide
- Salicylates
- Barbiturates
- Ipecac
- Cocaine
- Insulin
- Others

INFECTION AND INFLAMMATION (8) Complement C4A Complement C4B Interleukin-1RN (gene encoding IL-1 receptor antagonist [ra]; proinflammatory) Interleukin-6 (IL-6; proinflammatory) Interleukin-8 (IL-8; proinflammatory; associated with prone sleeping position) Interleukin-10 (IL-10) Vascular endothelial growth factor (VEGF) (proinflammatory) Tumor necrosis factor (TNF)-α (proinflammatory)	
OTHER (3) Mitochondrial DNA (mtDNA) polymorphisms (energy production) Flavin-monooxygenase 3 (*FMO3*) (enzyme metabolizes nicotine; risk factor with smoking mothers) Aquaporin-4 (T allele and CT/TT genotype associated with maternal smoking and with increased brain/body weight ratio in SIDS infants)	

Adapted from Hunt CE, Hauck FR: Sudden infant death syndrome: gene-environment interactions. In Brugada R, Brugada J, Brugada P, editors: Clinical care in inherited cardiac syndromes, *Guildford, UK, 2009, Springer-Verlag London.*

There is increasing evidence that infant deaths previously classified as SIDS are now being classified by medical examiners and coroners as from other causes, notably **accidental suffocation and strangulation in bed**. Between 1994 and 2004, there has been a quadrupling in the rates of accidental suffocation and strangulation in bed, from 2.8-12.5 deaths per 100,000 live births. These sudden and unexpected infant deaths are primarily associated with an unsafe sleeping environment such as prone position or in bed with parents. Based on these trends and the commonality of many of the sleep environment risk factors that are associated with both SIDS and other sleep-related SUID, risk reduction measures will be later described that are applicable to all sleep-related SUID.

PATHOLOGY

There are no autopsy findings pathognomonic for SIDS and no findings required for the diagnosis. There are some common findings. Petechial hemorrhages are found in 68-95% of cases and are more extensive than in explained causes of infant mortality. Pulmonary edema is often present and may be substantial. The reasons for these findings are unknown.

SIDS infants have several identifiable changes in the lungs and other organs and in brainstem structure and function. Nearly 65% of SIDS infants have structural evidence of preexisting, chronic, low-grade asphyxia, and other studies have identified biochemical markers of asphyxia. SIDS victims have higher levels of vascular endothelial growth factor (VEGF) in the cerebrospinal fluid. These increases may be related to VEGF polymorphisms (see "Genetic Risk Factors" below and Table 375-4) or might indicate recent hypoxemic events, because VEGF is upregulated by hypoxia. Brainstem findings include a persistent increase of dendritic spines and delayed maturation of synapses in the medullary respiratory centers, and decreased tyrosine hydroxylase immunoreactivity and catecholaminergic neurons. Cardiac muscle muscarinic receptor overexpression has also been reported in SIDS infants compared to infants who died from noncardiac causes. The regulatory mechanism may be related to increased acetylcholine esterase enzyme activity. The retrotrapezoid nucleus is one of the primary sites of central chemoreception and respiratory drive, and structural and/or PHOX2B-expression abnormalities have been reported in significantly more SIDS and other SUID cases than controls.

The ventral medulla has been a particular focus for studies in SIDS infants. It is an integrative area for vital autonomic functions including breathing, arousal, and chemosensory function. Quantitative 3-dimensional anatomic studies indicate that some SIDS infants have hypoplasia of the arcuate nucleus and up to 60% have histopathologic evidence of less-extensive bilateral or unilateral hypoplasia. Consistent with the apparent overlap between putative mechanisms for SIDS and for unexpected late fetal deaths, approximately 30% of late unexpected and unexplained stillbirths also have hypoplasia of the arcuate nucleus.

Neurotransmitter studies of the arcuate nucleus have also identified receptor abnormalities in some SIDS infants that involve several receptor types relevant to state-dependent autonomic control overall and to ventilatory and arousal responsiveness in particular. These deficits

include significant decreases in binding to kainate, muscarinic cholinergic, and serotonin (5-HT) receptors. Studies of the ventral medulla have identified morphologic and biochemical deficits in 5-HT neurons and decreased γ-aminobutyric acid receptor A receptor binding in the medullary serotonergic system. Immunohistochemical analyses reveal an increased number of 5-HT neurons and an increase in the fraction of 5-HT neurons showing an immature morphology, suggesting a failure or delay in the maturation of these neurons. High neuronal levels of interleukin-1β are present in the arcuate and dorsal vagal nuclei in SIDS victims compared to controls, perhaps contributing to molecular interactions affecting cardiorespiratory and arousal responses.

The neuropathologic data provide compelling evidence for altered 5-HT homeostasis, creating an underlying vulnerability contributing to SIDS. 5-HT is an important neurotransmitter and the 5-HT neurons in the medulla project extensively to neurons in the brainstem and spinal cord that influence respiratory drive and arousal, cardiovascular control including blood pressure, circadian regulation and non–rapid eye movement (REM) sleep, thermoregulation, and upper airway reflexes. Medullary 5-HT neurons may be respiratory chemosensors and may be involved with respiratory responses to intermittent hypoxia and respiratory rhythm generation. Decreases in 5-HT_{1A} and 5-HT_{2A} receptor immunoreactivity have been observed in the dorsal nucleus of the vagus, solitary nucleus, and ventrolateral medulla. There are extensive serotoninergic brainstem abnormalities in SIDS infants, including increased 5-HT neuronal count, a lower density of 5-HT_{1A} receptor-binding sites in regions of the medulla involved in homeostatic function, and a lower ratio of 5-HT transporter (5-HTT) binding density to 5-HT neuronal count in the medulla. Male SIDS infants have lower receptor-binding density than female SIDS infants. These findings suggest that the synthesis and availability of 5-HT is decreased within 5-HT pathways and hence impairs neuronal firing. Medullary tissue levels of 5-HT and its primary biosynthetic enzyme (tryptophan hydroxylase) were observed to be lower in SIDS cases compared to age-matched controls, indicating reduced 5-HT synthesis and hence a deficiency in 5-HT.

Table 375-5 Environmental Factors Associated with Increased Risk for Sudden Infant Death Syndrome

MATERNAL AND ANTENATAL RISK FACTORS
Elevated 2nd trimester serum α-fetoprotein
Smoking
Alcohol use
Drug use (cocaine, heroin)
Nutritional deficiency
Inadequate prenatal care
Low socioeconomic status
Younger age
Lower education
Single marital status
Shorter interpregnancy interval
Intrauterine hypoxia
Fetal growth restriction
INFANT RISK FACTORS
Age (peak 2-4 mo, but may be decreasing)
Male gender
Race and ethnicity (African-American and Native American, other minorities)
Growth failure
No breast-feeding
No pacifier (dummy)
Prematurity
Prone and side sleep position
Recent febrile illness (mild infections)
Inadequate immunizations
Smoking exposure (prenatal and postnatal)
Soft sleeping surface, soft bedding
Bed sharing with parent(s) or other children
Thermal stress, overheating
Colder season, no central heating

ENVIRONMENTAL RISK FACTORS

Declines of 50% or more in rates of SIDS in the United States and around the world have occurred following national education campaigns directed at reducing risk factors associated with SIDS. The reductions in risk appear to be related primarily to decreases in placing infants prone for sleep and increases in placing them supine. A number of other risk factors also have significant associations with SIDS (Table 375-5). Although many are nonmodifiable and most of the modifiable factors have not changed appreciably, self-reported maternal smoking prevalence during pregnancy has decreased by 25% in the past decade in the United States.

Nonmodifiable Environmental Risk Factors

Lower socioeconomic status has consistently been associated with higher risk, although SIDS affects infants from all social strata. In the United States, African-American, Native American, and Alaskan Native infants are 2-3 times more likely than white infants to die of SIDS, whereas Asian, Pacific Islander, and Hispanic infants have the lowest incidence. Some of this disparity may be related to the higher concentration of poverty and other adverse environmental factors found within some, but not all, of the communities with higher incidence.

Infants are at greatest risk of SIDS at 2-4 mo of age, with most deaths having occurred by 6 mo. This characteristic age has decreased in some countries as the SIDS incidence has declined, with deaths occurring at earlier ages and with a flattening of the peak age incidence. Similarly, the commonly observed winter seasonal predominance of SIDS has declined or disappeared in some countries as prone prevalence has decreased, supporting prior findings of an interaction between sleep position and factors more common in colder months (overheating as a consequence of elevated interior temperatures or bundling with blankets and heavy clothing, or infection). Male infants are 30-50% more likely to be affected than female infants.

Modifiable Environmental Risk Factors

Pregnancy-Related Factors

An increased SIDS risk is associated with numerous obstetric factors, suggesting that the in utero environment of future SIDS infants is suboptimal. SIDS infants are more commonly of higher birth order, independent of maternal age, and of gestations after shorter interpregnancy intervals. Mothers of SIDS infants generally receive less prenatal care and initiate care later in pregnancy. Additionally, low birthweight, preterm birth, and slower intrauterine and postnatal growth rates are risk factors.

Cigarette Smoking

There is a major association between intrauterine exposure to cigarette smoking and risk for SIDS. The incidence of SIDS is approximately 3 times greater among infants of mothers who smoke in studies conducted before SIDS risk-reduction campaigns and 5 times higher in studies after implementation of risk-reduction campaigns. The risk of death is progressively greater as daily cigarette use increases. The effects of smoking by the father and other household members are more difficult to interpret because they are highly correlated with maternal smoking. There appears to be a small independent effect of paternal smoking, but data on other household members have been inconsistent.

It is very difficult to assess the independent effect of infant exposure to **environmental tobacco smoke** because parental smoking behaviors during and after pregnancy are also highly correlated. An increased risk of SIDS is also found for infants exposed only to postnatal maternal environmental tobacco smoke. There is a dose–response for the number of household smokers, number of people smoking in the same room as the infant, and the number of cigarettes smoked. These data suggest that keeping the infant free of environmental tobacco smoke can further reduce an infant's risk of SIDS.

Drug and Alcohol Use

Most studies link maternal prenatal drug use, especially opiates, with an increased risk of SIDS, ranging from a 2-15–fold increased risk. Most but not all studies have not found an association between maternal alcohol use prenatally or postnatally and SIDS. In one study of Northern Plains Indians, periconceptional alcohol use and binge drinking in the 1st trimester were associated with a 6-fold and an 8-fold increased risk of SIDS, respectively. A Danish cohort study found that mothers admitted to the hospital for an alcohol- or drug-related disorder at any time before or after the birth of their infants had a 3-times higher risk of their infant dying from SIDS, and a Dutch study reported that maternal alcohol consumption in the 24 hr before the infant died carried a 2-8-fold increased risk of SIDS. Siblings of infants with fetal alcohol syndrome have a 10-fold increased risk of SIDS compared to controls.

Infant Sleep Environment

Sleeping prone has consistently been shown to increase the risk of SIDS. As rates of prone positioning have decreased in the general population, the odds ratios for SIDS in infants still sleeping prone have increased. **The highest risk of SIDS occurs in infants who are usually placed nonprone, but placed prone for last sleep ("unaccustomed prone") or found prone ("secondary prone").** The "unaccustomed prone" position may be more likely to occur in daycare or other settings outside the home and highlights the need for all infant caretakers to be educated about appropriate sleep positioning.

Side-sleeping is also a significant risk factor. The initial SIDS risk-reduction campaign recommendations considered side sleeping to be nearly equivalent to the supine position in reducing the risk of SIDS. Subsequent studies documented that side-sleeping infants were twice as likely to die of SIDS as infants sleeping supine. This increased risk might relate to the relative instability of the position, with some infants placed on the side rolling to the prone position. With the overall decrease in rates of placing infants prone for sleep, a higher proportion of SIDS is now attributed to being placed on the side for sleeping than for being placed prone. Nevertheless, the majority of SIDS occurrences are associated with being found prone. The **current recommendations** call for **supine position for sleeping for all infants except those few with specific medical conditions** for which recommending a different position may be justified, in particular infants with apparent anatomical or functional upper airway compromise.

Many parents and healthcare providers were initially concerned that supine sleeping would be associated with an increase in adverse consequences, such as difficulty sleeping, vomiting, or aspiration. Evidence suggests that the risk of regurgitation and choking is highest for prone-sleeping infants. Some newborn nursery staff still tend to favor side positioning, which models inappropriate infant care practice to parents. Infants sleeping on their backs do not have more episodes of cyanosis or apnea, and reports of apparent life-threatening events actually decreased in Scandinavia after increased use of the supine position. Among infants in the United States who maintained the same sleep position at 1, 3, and 6 mo of age, no clinical symptoms or reasons for outpatient visits (including fever, cough, wheezing, trouble breathing or sleeping, vomiting, diarrhea, or respiratory illness) were more common in infants sleeping supine or on their sides compared with infants sleeping prone. Three symptoms were actually less common in infants sleeping supine or on their sides: fever at 1 mo, stuffy nose at 6 mo, and trouble sleeping at 6 mo. Outpatient visits for ear infection were less common at 3 and 6 mo for infants sleeping supine and also less common at 3 mo for infants sleeping on their side. These results provide reassurance for parents and healthcare providers and should contribute to universal acceptance of supine as the safest and optimal sleep position for infants.

Soft sleep surfaces or bedding, such as comforters, pillows, sheepskins, polystyrene bean pillows, and older or softer mattresses are associated with increased risk of SIDS. **Head and face covering by loose bedding**, particularly heavy comforters, is also associated with increased risk. **Overheating** has been associated with increased risk for SIDS based on indicators such as higher room temperature, a febrile history, sweating, and excessive clothing or bedding. Some studies have identified an interaction between overheating and prone sleeping, with overheating increasing the risk of SIDS only when infants are sleeping prone. Higher external environmental temperatures have not been associated with increased SIDS incidence in the United States.

Several studies have implicated **bed sharing** as a risk factor for SIDS. Bed sharing is particularly hazardous when other children are in the same bed, when the parent is sleeping with an infant on a couch or other soft or confining sleeping surface, and when the mother smokes. Infants younger than 4 mo of age are at increased risk even when mothers are nonsmokers. A meta-analysis of 19 studies found that the low-risk infants (i.e., those who were breastfed and never exposed to cigarette smoke in utero or after birth) still had a 5-fold increased risk of SIDS until the age of 3 mo if bed sharing. Risk is also increased with longer duration of bed sharing during the night, whereas returning the infant to the infant's own crib has not been associated with increased risk. Room sharing without bed sharing is associated with lower SIDS rates, and is therefore recommended.

Infant Feeding Care Practices and Exposures

It is currently believed that there is a **protective effect of breastfeeding on SIDS**, after taking into account confounding factors. A meta-analysis found that there was a 45% reduction in SIDS after adjusting for confounding variables and that this protective effect increased for exclusive breastfeeding compared with partial breastfeeding.

Pacifier (dummy) use is associated with a lower risk of SIDS in the majority of studies when used for last sleep. Although it is not known if this is a direct effect of the pacifier itself or from associated infant or parental behavior, there is increasing evidence that pacifier use even with dislodgment can increase the arousability of infants during sleep. Concerns have been expressed about recommending pacifiers as a means of reducing the risk of SIDS for fear of adverse consequences, particularly interference with breastfeeding. Well-designed studies have found no association between pacifiers and breastfeeding duration.

Upper respiratory tract infections have generally not been found to be an independent risk factor for SIDS, but these and other minor infections may still have a role in the causal pathway of SIDS when other risk factors are present. Risk for SIDS has been found to be increased after illness among prone sleepers, those who were heavily wrapped, and those whose heads were covered during sleep.

No adverse association between immunizations and SIDS has been found. Indeed, SIDS infants are less likely to be immunized than control infants and, in immunized infants, no temporal relationship between vaccine administration and death has been identified. In a meta-analysis of case-control studies that adjusted for potentially confounding factors, the risk of SIDS for infants immunized with diphtheria, tetanus, and pertussis was half that for nonimmunized infants.

SIDS rates remain higher among Native Americans, Alaskan Natives, and African-Americans. This may be due, in part, to group differences in adopting supine sleeping or other risk-reduction practices. Greater efforts are needed to address this persistent disparity and to ensure that SIDS risk-reduction education reaches all parents and all other care providers, including other family members and personnel at daycare centers.

GENETIC RISK FACTORS

As summarized in Table 375-4, there are numerous genetic differences identified in SIDS infants compared to healthy infants and to infants dying from other causes. Polymorphisms occurring at higher incidence in SIDS compared to controls include at least 11 cardiac ion channelopathy genes that are proarrhythmic, 3 5-HT genes, 8 autonomic nervous system development genes, and 8 genes related to infection that are proinflammatory.

Multiple studies confirm the importance of a final common pathway that involves cardiac sodium or potassium channel dysfunction caused by direct or indirect disturbance resulting in **either long QT syndrome (LQTS)** or other arrhythmia associated with current dysfunction. LQTS is a known cause of sudden unexpected death in adults and

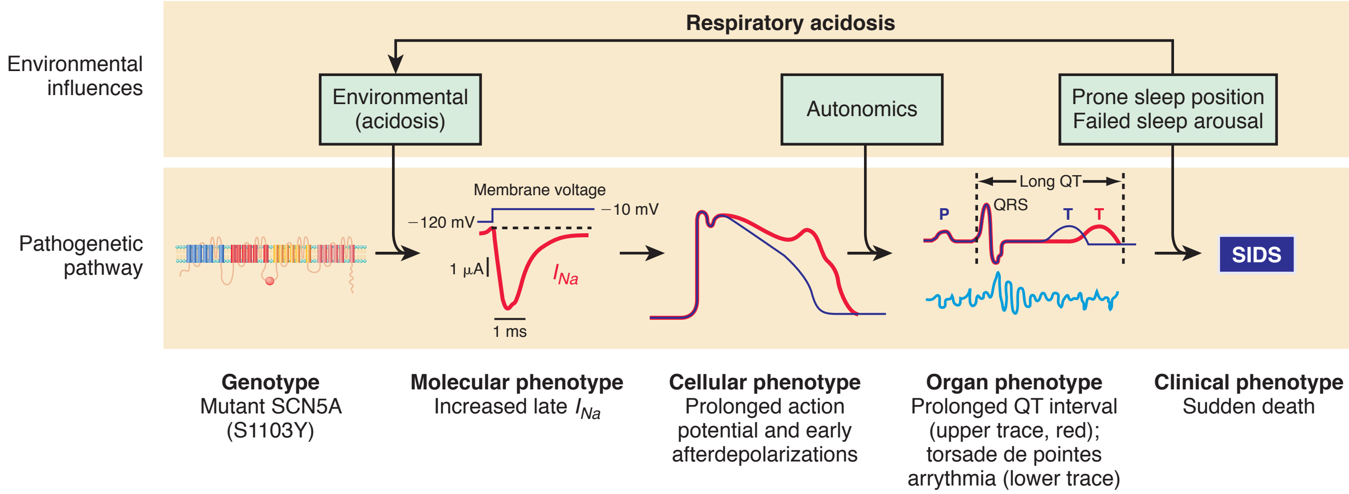

Figure 375-1 **An arrhythmogenic pathogenetic pathway for sudden infant death syndrome (SIDS) from patient genotype to clinical phenotype, with environmental influences noted.** The genetic abnormality—in this instance, a polymorphism in the cardiac Na^+ channel SCN5A—causes a molecular phenotype of increased late Na^+ current (I_{Na}) under the influence of environmental factors such as acidosis. Interacting with other ion currents that may themselves be altered by genetic and environmental factors, the late Na^+ current causes a cellular phenotype of prolonged action potential duration as well as early afterdepolarizations. Prolonged action potential in the cells of the ventricular myocardium and further interaction with environmental factors such as autonomic innervation, which, in turn, may be affected by genetic factors, produce a tissue-organ phenotype of a prolonged Q-T interval on the electrocardiogram (ECG) and torsades de pointes arrhythmia in the whole heart. If this is sustained or degenerates to ventricular fibrillation, the clinical phenotype of SIDS results. Environmental and multiple genetic factors can interact at many different levels to produce the characteristic phenotypes at the molecular, cellular, tissue, organ, and clinical levels. *(From Makielski JC: SIDS: genetic and environmental influences may cause arrhythmia in this silent killer,* J Clin Invest *116:297–299, 2006.)*

children, as the result of a prolonged cardiac action potential by either increasing depolarization or decreasing repolarization current (Fig. 375-1). The first evidence supporting a causal role for LQTS in SIDS was a large Italian study in which a corrected QT interval >440 milliseconds on an electrocardiogram performed on days 3-4 of life was associated with a 41.3 odds ratio for SIDS. Several case reports have subsequently provided proof of concept that cardiac channelopathy polymorphisms are associated with SIDS. LQTS is associated with polymorphisms related mainly to gain-of-function mutations in the **sodium channel gene** *(SCN5A)* that encode critical channel pore-forming α subunits or essential channel-interacting proteins. LQTS also is associated with mainly loss-of-function polymorphisms in potassium channel genes. **Short QTS (SQTS)** is more recently recognized as another cause of life-threatening arrhythmia or sudden death, often during rest or sleep. Gain-of-function mutations in genes including *KCNH2* and *KCNQ1* have been causally linked to SQTS, and some of these deaths have occurred in infants, suggesting that SQTS may also be causally linked to SIDS.

Both LQTS and SQTS are proarrhythmic and associated with cardiac arrest and sudden death. The other cardiac ion-related channelopathy polymorphisms are also proarrhythmic, including Brugada syndrome *(BrS1, BrS2),* and catecholaminergic paroxysmal ventricular tachycardia *(CPVT1).* Collectively, these mutations in cardiac ion channels provide a lethal arrhythmogenic substrate in some infants at risk for SIDS (see Fig. 375-1) and may account for 10% or more of SIDS cases.

Impaired central respiratory regulation is an important biologic abnormality in SIDS and genetic polymorphisms have been identified in SIDS infants that affect both serotonergic and adrenergic neurons. Monamine oxidase A metabolizes both of these neurotransmitters and a recent study has observed a high association between SIDS and low expressing alleles in males, perhaps contributing to the higher incidence of SIDS in males. Many genes are involved in the control of 5-HT synthesis, storage, membrane uptake, and metabolism. Polymorphisms have been identified in the promoter region of the 5-HT transporter (5-HTT) protein gene that occur in greater frequency in SIDS than control infants. The long "L" allele increased effectiveness of the promoter and reduced extracellular 5-HT concentrations at nerve endings compared to the short "S" allele. White, African-American, and Japanese SIDS infants were more likely than ethnicity-matched controls to have the "L" (long) allele, and there was also a negative association between SIDS and the S/S genotype. The L/L genotype was associated with increased 5-HT transporters on neuroimaging and postmortem binding studies. However, in a large San Diego dataset of SIDS infants, no relationship was found between SIDS and the L allele or the LL genotype.

An association has also been observed between SIDS and a 5-HTT intron 2 polymorphism, which differentially regulate *5-HTT* expression. There were positive associations between SIDS and the intron 2 genotype distributions in African-American infants compared to African-American controls. The human *FEV* gene is specifically expressed in central 5-HT neurons in the brain, with a predicted role in specification and maintenance of the serotoninergic neuronal phenotype. An insertion mutation has been identified in intron 2 of the *FEV* gene, and the distribution of this mutation differs significantly in SIDS compared to control infants.

Molecular genetic studies in SIDS victims have also identified mutations pertinent to early embryologic development of the autonomic nervous system (Table 375-4). Eleven protein-changing mutations have been identified in 14 of 92 SIDS cases among the *PHOX2a, RET, ECE1, TLX3,* and *EN1* genes. Only 1 of these mutations *(TLX3)* was found in 2 of 92 controls. African-American infants accounted for 10 of 11 mutations in SIDS infants and in both affected controls with protein-changing mutations. Eight polymorphisms in the *PHOX2B* gene occurred significantly more frequently in SIDS compared to control infants. One study has reported an association between SIDS and a distinct tyrosine hydroxylase gene (*THO1*) allele, which regulates gene expression and catecholamine production.

Genetic differences in SIDS infants compared to control infants have been reported for 2 complement *C4* genes. Some SIDS infants have loss-of-function polymorphisms in the gene promoter region for IL-10, another anti-inflammatory cytokine. Among SIDS infants compared to living controls, sudden infant death was strongly associated with the IL-10 polymorphism. These IL-10 polymorphisms were associated with decreased IL-10 levels and hence could contribute to SIDS by delaying initiation of protective antibody production or reducing capacity to inhibit inflammatory cytokine production. Other studies have not found differences in IL-10 genes in SIDS compared to

control infants, but one study did identify an association with the ATA haplotype in sudden and unexpected infant deaths classified as resulting from infection.

Polymorphisms associated with proinflammatory responses have also been found more frequently in SIDS infants compared to controls. An association was observed between single-nucleotide polymorphisms in the proinflammatory gene encoding interleukin (IL)-8 and SIDS infants sleeping prone compared to SIDS infants found in other sleep positions. IL-1 is another proinflammatory gene, and a higher prevalence has been reported in SIDS infants of the IL-1 receptor antagonist (IL-1RN), which would predispose to higher risk from infection. Significant associations with SIDS are reported for polymorphisms in VEGF, IL-6, and tumor necrosis factor-α. These 3 cytokines are proinflammatory, and these gain-of-function polymorphisms would result in increased inflammatory response to infectious or inflammatory stimuli and hence contribute to an imbalance between proinflammatory and antiinflammatory cytokines. As apparent proof of principle, elevated levels of IL-6 and VEGF have been reported from cerebrospinal fluid in SIDS infants. There were no group differences in the IL6-174G/C polymorphism in a Norwegian SIDS study, but the aggregate evidence nevertheless suggests an activated immune system in SIDS and thus implicates genes involved in the immune system. Almost all SIDS infants in 1 study had positive histories for prone sleeping and fever prior to death and positive HLA-DR expression in laryngeal mucosa, and high HLA-DR expression was associated with high levels of IL-6 in cerebrospinal fluid.

Numerous reports have implicated polymorphisms in genes regulating energy production in SIDS infants, but the importance of these findings requires further study (Table 375-4). Of interest, cardiac arrhythmias, including prolonged QT intervals, have been observed in families with mitochondrial disease. However, the mitochondrial DNA polymorphism T3394C that is associated with cardiac arrhythmia has not been observed to occur with greater frequency in SIDS compared to control infants.

GENE-AND-ENVIRONMENT INTERACTIONS

Interactions between genetic and environmental risk factors determine the actual risk for SIDS in individual infants (Fig. 375-2). There appears to be an interaction between prone sleep position and impaired ventilatory and arousal responsiveness. Facedown or nearly facedown sleeping does occasionally occur in prone-sleeping infants, but normal healthy infants arouse before such episodes become life-threatening. Infants with insufficient arousal responsiveness to asphyxia, however, may be at risk for sudden death from resulting episodes of airway obstruction and asphyxia. There may also be links between modifiable risk factors such as soft bedding, prone sleep position, and thermal stress, and links between genetic risk factors such as ventilatory and arousal abnormalities and temperature or metabolic regulation deficits. Cardiorespiratory control deficits could be related to 5-HTT polymorphisms, for example, or to polymorphisms in genes pertinent to autonomic nervous system development. Affected infants could be at increased risk for sleep-related hypoxemia and hence more susceptible to adverse effects associated with unsafe sleep position or bedding. Infants at increased risk for sleep-related hypoxemia could also be at greater risk for fatal arrhythmias in the presence of a cardiac ion channelopathy polymorphism.

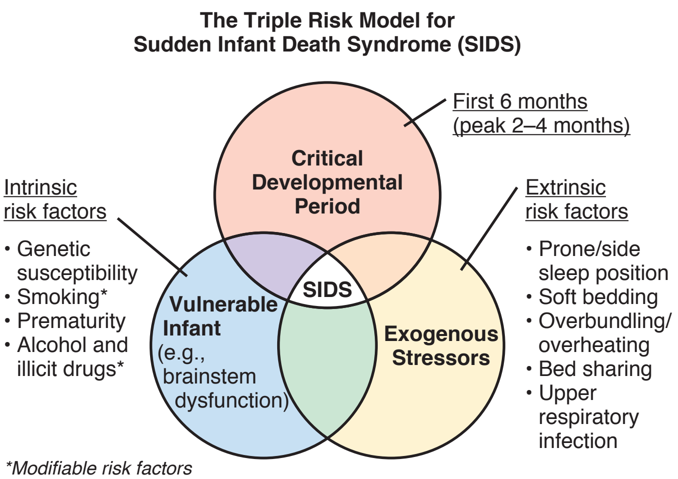

Figure 375-2 Schematic of the triple-risk model for sudden infant death syndrome (SIDS) showing the critical interactions between intrinsic risk factors (including genetic risk factors) resulting in a vulnerable infant, a critical developmental period or age, and exogenous stressors or extrinsic risk factors. *(Adapted from Filiano JJ, Kinney HC: A perspective on the neuropathologic findings in victims of the sudden infant death syndrome: the triple risk model,* Biol Neonate *65:194–197, 1994.)*

In >50% of SIDS victims, recent febrile illnesses, often related to upper respiratory infection, have been documented (see Table 375-5). Otherwise benign infections might increase risk for SIDS if interacting with genetically determined impaired immune responses, including those resulting from partial deletions in the complement C4 gene or to interleukin polymorphisms (see Table 375-4). Deficient inflammatory responsiveness can also occur as a result of mast cell degranulation, which has been reported in SIDS infants; this is consistent with an anaphylactic reaction to a bacterial toxin, and some family members of SIDS infants also have mast cell hyperreleasability and degranulation, suggesting that increased susceptibility to an anaphylactic reaction is another genetic factor influencing fatal outcomes to otherwise minor infections in infants. Interactions between upper respiratory infections or other minor illnesses and other factors such as prone sleeping might also play a role in the pathogenesis of SIDS.

The increased risk for SIDS associated with fetal and postnatal exposure to cigarette smoke may be related at least in part to genetic or epigenetic factors, including those affecting brainstem autonomic control. Human infant studies document decreased ventilatory and arousal responsiveness to hypoxia following fetal nicotine exposure, and impaired autoresuscitation after apnea has been associated with postnatal nicotine exposure. Decreased brainstem immunoreactivity to selected protein kinase C and neuronal nitric oxide synthase isoforms occurs in rats exposed to cigarette smoke prenatally, another potential cause of impaired hypoxic responsiveness. Smoking exposure also increases susceptibility to viral and bacterial infections and increases bacterial binding after passive coating of mucosal surfaces with smoke components, implicating interactions between smoking, cardiorespiratory control, and immune status. Flavin-monooxygenase 3 (*FMO3*) is one of the enzymes that metabolizes nicotine, and a polymorphism has recently been identified that occurs more frequently in SIDS infants compared to controls and more frequently in infants whose mothers reported heavy smoking (Table 375-4). This polymorphism thus provides a potential genetic risk factor for SIDS in infants exposed to cigarette smoke.

In infants with a cardiac ion channelopathy, risk for a fatal arrhythmia during sleep may be substantially enhanced by predisposing perturbations that increase electrical instability. These perturbations could include REM sleep with bursts of vagal and sympathetic activation, minor respiratory infections, or any other cause of sleep-related hypoxemia or hypercarbia, especially those resulting in acidosis. The prone sleeping position is associated with increased sympathetic activity.

INFANT GROUPS AT INCREASED RISK FOR SUDDEN INFANT DEATH SYNDROME

Unexplained Apparent Life-Threatening Events

Infants with an unexplained **apparent life-threatening event (ALTE)** are at increased risk for SIDS. An ALTE is defined as an episode that frightens an observer and manifests with some combination of central, obstructive, or mixed apnea; cyanotic, pallid, plethora, erythematous, color change; hypotonia (rarely hypertonia); and choking or gasping. A history of an unexplained ALTE has been reported in 5-9% of SIDS victims, and the risk of SIDS appears to be higher with 2 or more

unexplained events, but no definitive incidence rates are available. Compared with healthy control infants, the risk for SIDS may be as much as 3-5 times greater in infants having experienced an ALTE. Although most studies of ALTE have not specified gestational age, 30% of ALTE infants in the Collaborative Home Infant Monitoring Evaluation were ≤37 wk gestation at birth.

Subsequent Siblings of a Sudden Infant Death Syndrome Victim

The next-born siblings of first-born infants dying of any noninfectious natural cause are at significantly increased risk for infant death from the same cause, including SIDS. The relative risk is 9.1 for the same cause of recurrent death vs 1.6 for a different cause of death. The relative risk for recurrent SIDS (range: 5.4-5.8) is similar to the relative risk for non-SIDS causes of recurrent death (range: 4.6-12.5). The risk for recurrent infant mortality from the same cause as in the index sibling thus appears to be increased to a similar degree in subsequent siblings for both explained causes and for SIDS. This increased risk for recurrent SIDS in families is consistent with genetic risk factors interacting with environmental risk factors (see Tables 375-4 and 375-5 and Fig. 375-2).

Prematurity

Despite reductions in SIDS and SUID among infants born preterm by more than 50% since initiation of the back-to-sleep campaign in the United States 20 yr ago, the risk for death remains significantly higher than for infants born full term. This increased risk is likely related in part to immaturity of brainstem ventilatory control. Also, although the environmental risk factors for SIDS and SUID are qualitatively similar to those in full-term infants, including nonsupine sleeping position and other unsafe sleep practices, infants born preterm do have more sociodemographic risk factors overall than infants born at term. Among all gestational age groups, the postnatal age of death from SIDS and other SUID progressively decreases as gestational age at birth increases, and the postmenstrual age at death progressively increases as gestational age at birth increases. Compared with infants born at 37-42 wk, the odds ratio for SIDS is greatest for infants born at 24-28 wk gestation (2.57, 95% confidence interval 2.08, 3.17). The odds ratio progressively decreases as gestational age at birth increases, but even at 33-36 wk gestational age at birth remains significantly increased compared to infants born at term.

Physiologic Studies

Physiologic studies have been performed in healthy infants in early infancy, a few of whom later died of SIDS. Physiologic studies have also been performed on infant groups at increased risk for SIDS, especially those with ALTE and subsequent siblings of SIDS. In the aggregate, these studies have indicated brainstem abnormalities in neuroregulation of cardiorespiratory control or other autonomic functions and are consistent with the autopsy findings and genetic studies in SIDS victims (see "Pathology" and "Genetic Risk Factors" above). In addition to chemoreceptor sensitivity, these observed physiologic abnormalities also include respiratory patterns, control of heart and respiratory rate or variability, and asphyxic arousal responsiveness. A deficit in arousal responsiveness may be a necessary prerequisite for SIDS to occur but may be insufficient to cause SIDS in the absence of other genetic or environmental risk factors. **Autoresuscitation (gasping)** is a critical component of the asphyxic arousal response, and a failure of autoresuscitation in SIDS infants may be the final and most devastating physiologic failure. Most normal full-term infants younger than 9 postnatal wk of age in 1 study aroused in response to mild hypoxia, but only 10-15% aroused if older than 9 wk of age. These data thus suggest that ability to arouse to mild to moderate hypoxic stimuli may be at a nadir at the age range of greatest risk for SIDS.

The ability to shorten the QT interval as heart rate increases appears to be impaired in some SIDS victims, suggesting that such infants may be predisposed to ventricular arrhythmia. This is consistent with the observations of cardiac ion channel gene polymorphisms in other SIDS victims (see Table 375-4), but there are no antemortem QT interval data in the SIDS infants having postmortem channelopathy polymorphisms. Infants studied physiologically and dying of SIDS a few weeks later had higher heart rates in all sleep–wake states, diminished heart rate variability during wakefulness, and significantly lower heart rate variability at the respiratory frequency across all sleep–wake cycles. Also, these SIDS infants had longer QT intervals than control infants in both REM and non-REM sleep, especially in the late hours of the night when most SIDS likely occurs. In only 1 of these SIDS infants, however, did the QT interval exceed 440 milliseconds.

Part of the decreased heart rate variability and increased heart rate observed in infants who later died of SIDS may have been related to decreased vagal tone, perhaps at least in part related to vagal neuropathy or to brainstem damage in areas responsible for parasympathetic cardiac control. In a comparison of heart rate power spectra before and after obstructive apneas in clinically asymptomatic infants, infants later dying of SIDS did not have the decreases in low-frequency to high-frequency power ratios observed in infants who survived. Some future SIDS victims thus have different autonomic responsiveness to obstructive apnea, perhaps indicating impaired autonomic nervous system control associated with higher vulnerability to external or endogenous stress factors and hence to reduced electrical stability of the heart.

Home cardiorespiratory monitors with memory capability have recorded the terminal events in some SIDS victims. These recordings did not include pulse oximetry and could not identify obstructed breaths due to reliance on transthoracic impedance for breath detection. In most instances, there has been sudden and rapid progression of severe bradycardia that was either unassociated with central apnea or appeared to occur too soon to be explained by the central apnea. These observations are consistent with an abnormality in autonomic control of heart rate variability, or with obstructed breaths resulting in bradycardia or hypoxemia and associated with impaired autoresuscitation or arousal.

CLINICAL STRATEGIES

Home Monitoring

SIDS cannot be prevented in individual infants because it is not possible to identify prospective SIDS infants, and no effective intervention has been established even if SIDS infants could be prospectively identified. Studies of cardiorespiratory pattern or other autonomic abnormalities do not have sufficient sensitivity and specificity to be clinically useful as screening tests. Home electronic surveillance using existing technology does not reduce the risk of SIDS. Although a prolonged QT interval in an infant may be treated if diagnosed, neither the role of routine postnatal electrocardiographic screening, the cost-effectiveness of diagnosis and treatment, nor the safety of treatment in infants has been established (see Chapter 429). Parental electrocardiographic screening is not helpful because spontaneous mutations are common.

Reducing the Risk of Sudden Infant Death Syndrome

Reducing risk behaviors and increasing protective behaviors among infant caregivers to achieve further reductions and eventual elimination of SIDS is a critical goal. Recent plateaus in placing infants supine for sleep in the United States at approximately 75% for all races and only 56% for African-Americans are cause for concern and require renewed educational efforts. The American Academy of Pediatrics guidelines to reduce the risk of SIDS were updated in 2011 and expanded to include reducing the risk of all sudden and unexpected sleep-related infant deaths. The guidelines are appropriate for most infants, but physicians and other healthcare providers might, on occasion, need to consider alternative approaches. The major components of the American Academy of Pediatrics guidelines are:

- Full-term and premature infants should be placed for sleep in the supine position. There are no adverse health outcomes from supine sleeping. Side sleeping is not recommended.
- It is recommended that infants sleep in the same room as their parents but in their own crib or bassinette that conforms to the

safety standards of the Consumer Product Safety Commission. Placing the crib or bassinette near the mother's bed facilitates nursing and contact.

- Infants should be put to sleep on a firm mattress. Waterbeds, sofas, soft mattresses, or other soft surfaces should not be used. In addition, car seats, strollers, swings and other sitting devices should not be used for sleeping. Sleeping in an upright position can lead to gastroesophageal reflux or upper airway obstruction from head flexion.
- Soft materials in the infant's sleep environment—over, under, or near the infant—should be avoided. These include pillows, comforters, quilts, sheepskins, bumper pads, and stuffed toys. Because loose bedding may be hazardous, blankets, if used, should be tucked in around the crib mattress. Sleeping clothing, such as a sleep sack, can be used in place of blankets.
- Avoid overheating and overbundling. The infant should be lightly clothed for sleep and the thermostat set at a comfortable temperature.
- Infants should be immunized in accordance with recommendations of the American Academy of Pediatrics and the Centers for Disease Control and Prevention. There is no evidence that immunizations increase risk for SIDS. Indeed, recent evidence suggests that immunizations may have a protective effect against SIDS.
- Healthcare professionals, staff in newborn nurseries and neonatal intensive care units, and child care providers should adopt the SIDS reduction recommendations beginning at birth.
- Infants should have some time in the prone position (tummy time) while awake and observed. Alternating the placement of the infant's head as well as his or her orientation in the crib can also minimize the risk of head flattening from supine sleeping (positional plagiocephaly).
- Devices advertised to maintain sleep position, "protect" a bed-sharing infant, or reduce the risk of rebreathing are not recommended.
- Home cardiorespiratory and/or O_2 saturation monitoring may be of value for selected infants who have extreme instability, but there is no evidence that monitoring decreases the incidence of SIDS and it is therefore not recommended for this purpose.
- Breastfeeding is recommended. If possible, mothers should exclusively breastfeed or feed with expressed human milk until the infant is 6 mo of age.
- If a breastfeeding mother brings the infant into the adult bed for nursing, the infant should be returned to a separate sleep surface when the mother is ready for sleep.
- Consider offering a pacifier at bedtime and naptime. The pacifier should be used when placing the infant down for sleep and need not be reinserted once it falls out. For breastfed infants, delay introduction of the pacifier until breastfeeding is well established.
- Mothers should not smoke, drink alcohol, or use illicit drugs during pregnancy or after birth, and infants should not be exposed to secondhand smoke.
- The national Back to Sleep campaign should be expanded to emphasize the multiple characteristics of a safe sleeping environment and to focus on the groups with continuing higher rates of SIDS. Educational strategies must be tailored to each racial or ethnic group to ensure acceptance within that cultural context. Secondary care providers need to be targeted to receive these educational messages, including daycare providers, grandparents, foster parents, and babysitters.
- Research and surveillance should be continued on the risk factors, causes and pathophysiological mechanisms of SIDS and other sleep-related SUID, with the ultimate goal of preventing these deaths entirely. Federal and private funding agencies need to remain committed to this research.

Section 2

Disorders of the Respiratory Tract

Chapter 376

Congenital Disorders of the Nose

Joseph Haddad Jr. and Sarah Keesecker

NORMAL NEWBORN NOSE

In contrast to children and adults who preferentially breathe through their nose unless nasal obstruction interferes, most newborn infants are obligate nasal breathers and significant nasal obstruction presenting at birth, such as choanal atresia, may be a life-threatening situation for the infant unless an alternative to the nasal airway is established. Nasal congestion with obstruction is common in the 1st yr of life and can affect the quality of breathing during sleep; it may be associated with a narrow nasal airway, viral or bacterial infection, enlarged adenoids, or maternal estrogenic stimuli similar to rhinitis of pregnancy. The internal nasal airway doubles in size in the 1st 6 mo of life, leading to resolution of symptoms in many infants. Supportive care with a bulb syringe and saline nose drops, topical nasal decongestants, and antibiotics, when indicated, improve symptoms in affected infants.

PHYSIOLOGY

The nose is responsible for the initial warming and humidification of inspired air and olfaction. In the anterior nasal cavity, turbulent airflow and coarse hairs enhance the deposition of large particulate matter; the remaining nasal airways filter out particles as small as 6 μm in diameter. In the turbinate region, the airflow becomes laminar and the airstream is narrowed and directed superiorly, enhancing particle deposition, warming, and humidification. Nasal passages contribute as much as 50% of the total resistance of normal breathing. Nasal flaring, a sign of respiratory distress, reduces the resistance to inspiratory airflow through the nose and can improve ventilation (see Chapter 373).

Although the nasal mucosa is more vascular (especially in the turbinate region) than in the lower airways, the surface epithelium is similar, with ciliated cells, goblet cells, submucosal glands, and a covering blanket of mucus. The nasal secretions contain lysozyme and secretory immunoglobulin (Ig) A, both of which have antimicrobial activity, and IgG, IgE, albumin, histamine, bacteria, lactoferrin, and cellular debris, as well as mucous glycoproteins, which provide viscoelastic properties. Aided by the ciliated cells, mucus flows toward the nasopharynx, where the airstream widens, the epithelium becomes squamous, and secretions are wiped away by swallowing. Replacement of the mucous layers occurs about every 10-20 min. Estimates of daily mucus production vary from 0.1-0.3 mg/kg/24 hr, with most of the mucus being produced by the submucosal glands.

CONGENITAL DISORDERS

Congenital *structural nasal malformations* are uncommon compared with acquired abnormalities. The nasal bones can be congenitally absent so that the bridge of the nose fails to develop, resulting in *nasal hypoplasia*. Congenital absence of the nose *(arhinia)*, complete or partial duplication, or a single centrally placed nostril can occur in isolation but is usually part of a malformation syndrome. Rarely,

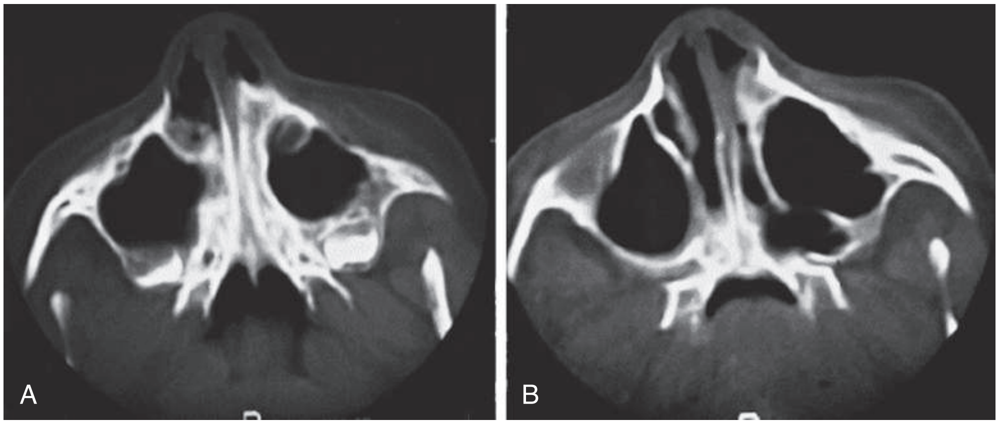

Figure 376-1 CT scan showing **(A)** hypoplastic nasal cavities and **(B)** bony and mucosal choanal atresia. *(From Altuntas A, Yilmaz MD, Kahveci OK, et al: Coexistence of choanal atresia and Tessier's facial cleft number 2,* Int J Pediatr Otorhinolaryngol *68:1081–1085, 2004.)*

supernumerary teeth are found in the nose, or teeth grow into it from the maxilla.

Nasal bones can be sufficiently malformed to produce severe narrowing of the nasal passages. Often, such narrowing is associated with a high and narrow hard palate. Children with these defects can have significant obstruction to airflow during infections of the upper airways and are more susceptible to the development of chronic or recurrent hypoventilation (see Chapter 19). Rarely, the alae nasi are sufficiently thin and poorly supported to result in inspiratory obstruction, or there may be congenital nasolacrimal duct obstruction with cystic extension into the nasopharynx, causing respiratory distress.

CHOANAL ATRESIA

This is the most common congenital anomaly of the nose and has a frequency of approximately 1 in 7,000 live births. It consists of a unilateral or bilateral bony (90%) or membranous (10%) septum between the nose and the pharynx; most cases are a combination of bony and membranous atresia. The pathogenesis is unknown but theories include persistence of the buccopharyngeal membranes or failure of the oronasal membrane to rupture. The unilateral defect is more common and the female : male ratio is approximately 2 : 1. Approximately 50-70% of affected infants have other congenital anomalies (CHARGE syndrome, Treacher-Collins, Kallmann syndrome, VATER [vertebral defects, imperforate anus, tracheoesophageal fistula, and renal defects] association, Pfeiffer syndrome), with the anomalies occurring more often in bilateral cases. The **CHARGE syndrome** (*c*oloboma, *h*eart disease, *a*tresia choanae, *r*etarded growth and development or central nervous system anomalies or both, *g*enital anomalies or hypogonadism or both, and *e*ar anomalies or deafness or both) is one of the more common anomalies associated with choanal atresia—approximately 10-20% of patients with choanal atresia have it. Most patients with CHARGE syndrome have mutations in the *CHD7* gene, which is involved in chromatin organization.

Clinical Manifestations

Newborn infants have a variable ability to breathe through their mouths, so nasal obstruction does not produce the same symptoms in every infant. When the obstruction is unilateral, the infant may be asymptomatic for a prolonged period, often until the first respiratory infection, when unilateral nasal discharge or persistent nasal obstruction can suggest the diagnosis. Infants with bilateral choanal atresia who have difficulty with mouth breathing make vigorous attempts to inspire, often suck in their lips, and develop cyanosis. Distressed children then cry (which relieves the cyanosis) and become calmer, with normal skin color, only to repeat the cycle after closing their mouths. Those who are able to breathe through their mouths at once experience difficulty when sucking and swallowing, becoming cyanotic when they attempt to feed.

Diagnosis

Diagnosis is established by the inability to pass a firm catheter through each nostril 3-4 cm into the nasopharynx. The atretic plate may be seen directly with fiberoptic rhinoscopy. The anatomy is best evaluated by using high-resolution CT (Fig. 376-1).

Treatment

Initial treatment consists of prompt placement of an oral airway, maintaining the mouth in an open position, or intubation. A standard oral airway (such as that used in anesthesia) can be used, or a feeding nipple can be fashioned with large holes at the tip to facilitate air passage. Once an oral airway is established, the infant can be fed by gavage until breathing and eating without the assisted airway is possible. In bilateral cases, intubation or, less often, tracheotomy may be indicated. If the child is free of other serious medical problems, operative intervention is considered in the neonate; transnasal repair is the treatment of choice, with the introduction of small magnifying endoscopes and smaller surgical instruments and drills. Stents are usually left in place for weeks after the repair to prevent closure or stenosis. Tracheotomy should be considered in cases of bilateral atresia in which the child has other potentially life-threatening problems and in whom early surgical repair of the choanal atresia may not be appropriate or feasible. Operative correction of unilateral obstruction may be deferred for several years. In both unilateral and bilateral cases, restenosis necessitating dilation or reoperation, or both, is common. Mitomycin C has been used to help prevent the development of granulation tissue and stenosis.

CONGENITAL DEFECTS OF THE NASAL SEPTUM

Perforation of the septum is most commonly acquired after birth secondary to infection, such as syphilis or tuberculosis, or trauma; rarely, it is developmental. Continuous positive airway pressure cannulas are a cause of iatrogenic perforation. Trauma from delivery is the most common cause of septal deviation noted at birth. When recognized early, it can be corrected with immediate realignment using blunt probes, cotton applicators, and topical anesthesia. Formal surgical correction, when required, is usually postponed to avoid disturbance of midface growth.

Mild septal deviations are common and usually asymptomatic; abnormal formation of the septum is uncommon unless other malformations are present, such as cleft lip or palate.

PYRIFORM APERTURE STENOSIS

Infants with this bony abnormality of the anterior nasal aperture present at birth or shortly thereafter with severe nasal obstruction leading to noisy breathing and respiratory distress that worsen with feeding and improve with crying. It can occur in isolation or in association with other malformations including holoprosencephaly,

Nasal Pyriform Stenosis

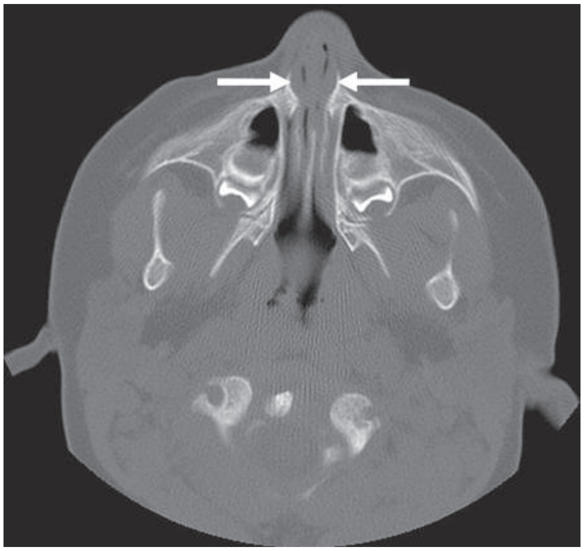

Figure 376-2 CT scan of a child who has congenital nasal pyriform aperture stenosis. Note the inward bowing of the nasal processes of the maxillary bone with the pyriform aperture measuring 7 mm *(arrows). (From Tate JR, Sykes J. Congenital nasal pyriform aperture stenosis.* Otolaryngol Clin North Am *42(3):521–525, 2009, Fig. 2.)*

hypopituitarism, and cardiac and urogenital malformations. Diagnosis is made by CT of the nose (Fig. 376-2). Medical management (nasal decongestants, humidification, nasopharyngeal airway insertion, management of reflux) can be used but surgical repair by means of an anterior, sublabial approach may be needed if the child cannot feed or breathe without difficulty. A drill is used to enlarge the stenotic anterior bone apertures.

CONGENITAL MIDLINE NASAL MASSES

Dermoids, gliomas, and *encephaloceles* (in descending order of frequency) occur intranasally or extranasally and can have intracranial connections or extend intracranially with communication to the subarachnoid space. The theory for the embryologic development of congenital midline nasal masses is faulty retraction of the dural diverticulum. Dermoids and epidermoids are the most common type of congenital midline nasal mass and have been reported to represent up to 61% of lesions. Nasal dermoids often have a dimple or pit on the nasal dorsum, sometimes with hair being present, and can predispose to intracranial infections if an intracranial fistula or sinus is present. Recurrent infection of the dermoid itself is more common. Gliomas or heterotopic brain tissue are firm, whereas encephaloceles are soft and enlarge with crying or the Valsalva maneuver. Diagnosis is based on physical examination findings and results from imaging studies. CT provides the best bony detail, but MRI is helpful also because of its superior ability to define intracranial extension (Fig. 376-3). Surgical excision of these masses is generally required, with the extent and surgical approach based on the type and size of the mass.

Other nasal masses include *hemangiomas, congenital nasolacrimal duct obstruction* (which can occur as an intranasal mass), nasal polyps, and tumors such as rhabdomyosarcoma (see Chapter 500). Nasal polyps are rarely present at birth, but the other masses often present at birth or in early infancy (see Chapter 378).

Poor development of the paranasal sinuses and a narrow nasal airway are associated with recurrent or chronic upper airway infection in Down syndrome (see Chapter 81).

DIAGNOSIS AND TREATMENT

In children with congenital nasal disorders, supportive care of the airway is given until the diagnosis is established. Diagnosis is made through a combination of flexible scoping and imaging studies,

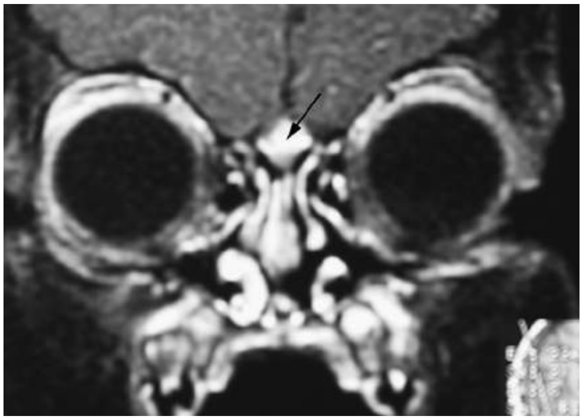

Figure 376-3 Coronal CT scan of nasal dermoid with intracranial extension (arrow). *(From Manning SC, Bloom DC, Perkins JA, et al: Diagnostic and surgical challenges in the pediatric skull base. Otolaryngol Clin North Am 38:773-794, 2005. Fig. 2.)*

primarily CT scan. In the case of surgically correctable congenital problems such as choanal atresia, surgery is performed once the child is deemed healthy and free of life-threatening problems such as congenital heart disease.

Chapter 377

Acquired Disorders of the Nose

Joseph Haddad Jr. and Sarah Keesecker

Tumors, septal perforations, and other acquired abnormalities of the nose and paranasal sinuses can manifest with epistaxis. Midface trauma with a nasal or facial fracture may be accompanied by epistaxis. Trauma to the nose can cause a *septal hematoma;* if treatment is delayed, this can lead to necrosis of septal cartilage and a resultant *saddle-nose deformity.* Other abnormalities that can cause a change in the shape of the nose and paranasal bones, with obstruction but few other symptoms, include *fibroosseous lesions* (ossifying fibroma, fibrous dysplasia, cementifying fibroma) and *mucoceles of the paranasal sinuses.* These conditions may be suspected on physical examination and confirmed by CT scan and biopsy. Although these are considered benign lesions, they can all greatly change the anatomy of surrounding bony structures and often require surgical intervention for management.

377.1 Foreign Body

Joseph Haddad Jr. and Sarah Keesecker

ETIOLOGY

Foreign bodies (food, beads, crayons, small toys, erasers, paper wads, buttons, batteries, beans, stones, pieces of sponge, and other small objects) are often placed in the nose by small children and developmentally delayed children and constitute ≤1% of pediatric emergency department visits. Nasal foreign bodies can go unrecognized for long periods of time because they initially produce few symptoms and

are difficult to visualize. First symptoms include unilateral obstruction, sneezing, relatively mild discomfort, and, rarely, pain. Presenting clinical symptoms include history of insertion of foreign bodies (86%), mucopurulent nasal discharge (24%), foul nasal odor (9%), epistaxis (6%), nasal obstruction (3%), and mouth breathing (2%). Irritation results in mucosal swelling because some foreign bodies are hygroscopic and increase in size as water is absorbed; signs of local obstruction and discomfort can increase with time. The patient might also present with a generalized body odor known as *bromhidrosis.*

DIAGNOSIS

Unilateral nasal discharge and obstruction should suggest the presence of a foreign body, which can often be seen on examination with a nasal speculum or wide otoscope placed in the nose. Purulent secretions may have to be cleared so that the foreign object can actually be seen; a headlight, suction, and topical decongestants are often needed. The object is usually situated anteriorly, but unskilled attempts at removal can force the object deeper into the nose. A long-standing foreign body can become embedded in granulation tissue or mucosa and appear as a nasal mass. A lateral skull radiograph assists in diagnosis if the foreign body is metallic or radiopaque.

TREATMENT

A quick examination of the nose is made to determine if a foreign body is present, and whether it needs to be removed emergently. Planning is then made for office or operating room extrication of the foreign body. Prompt removal minimizes the danger of aspiration and local tissue necrosis. This can usually be performed with topical anesthesia, using either forceps or nasal suction. Alternatively, a Katz catheter (made specifically for the removal of foreign bodies from the nose and ear) can be inserted above and distal to the object, inflated, and drawn back with gentle traction.

The "mother kiss" approach has been successful in acute situations where a person occludes the unaffected nostril and then, with a complete seal over the child's mouth attempts to dislodge the foreign body by blowing into the mouth. A similar approach uses an Ambu bag over the mouth with the unaffected nostril occluded. If there is marked swelling, bleeding, or tissue overgrowth, general anesthesia may be needed to remove the object. Infection usually clears promptly after the removal of the object and, generally, no further therapy is necessary. Magnets can be used to extract metal foreign bodies, 2% lidocaine can be used to kill live insects before removal, and irrigation should be avoided with vegetable matter or sponges because of the risk of foreign-body swelling.

COMPLICATIONS

Serious complications include posterior dislodgement and aspiration, trauma caused by the object itself or removal attempts, infection, and choanal stenosis. Infection is common and gives rise to a purulent, malodorous, or bloody discharge. Local tissue damage from long-standing foreign body, or alkaline injury from a disk battery, can lead to local tissue loss and cartilage destruction. A synechia or scar band can then form, causing nasal obstruction. Loss of septal mucosa and cartilage can cause a septal perforation. Disk batteries are especially dangerous when placed in the nose; they leach base, which causes pain and local tissue destruction in a matter of hours. Magnets also carry a risk of septal perforation and necrosis.

Tetanus is a rare complication of long-standing nasal foreign bodies in nonimmunized children (see Chapter 211). Toxic shock syndrome is also rare and most commonly occurs from nasal surgical packing (see Chapter 181.2); oral antibiotics should be administered when nasal surgical packing is placed.

PREVENTION

Tempting objects, such as round, shiny beads, should only be used under adult supervision. Disk batteries should be stored away from the reach of small children.

Bibliography is available at Expert Consult.

377.2 Epistaxis

Joseph Haddad Jr. and Sarah Keesecker

Although rare in infancy, nosebleeds are common in children older than 2 yr of age. Their incidence decreases after puberty. Diagnosis and treatment depend on the location and cause of the bleeding.

ANATOMY

The most common site of bleeding is the Kiesselbach plexus, an area in the anterior septum where vessels from both the internal carotid (anterior and posterior ethmoid arteries) and external carotid (sphenopalatine and terminal branches of the internal maxillary arteries) converge. The thin mucosa in this area, as well as the anterior location, make it prone to exposure to dry air and trauma.

ETIOLOGY

Epistaxis can be classified into primary or secondary based on cause and this has implications for diagnosis and management. Common causes of nosebleeds from the anterior septum include digital trauma, foreign bodies, dry air, and inflammation, including upper respiratory tract infections, sinusitis, and allergic rhinitis (Table 377-1). There is often a family history of childhood epistaxis. Nasal steroid sprays are commonly used in children, and their chronic use may be associated with nasal mucosal bleeding. Young infants with significant gastroesophageal reflux into the nose rarely present with epistaxis secondary to mucosal inflammation. Susceptibility is increased during respiratory infections and in the winter when dry air irritates the nasal mucosa, resulting in formation of fissures and crusting. Severe bleeding may be encountered with congenital vascular abnormalities, such as *hereditary hemorrhagic telangiectasia* (see Chapter 432.3), varicosities, hemangiomas, and, in children with thrombocytopenia, deficiency of clotting factors, particularly von Willebrand disease (see Chapter 477), hypertension, renal failure, or venous congestion. Recurrent epistaxis despite cauterization is associated with mild coagulation disorders. The family history may be positive for abnormal bleeding (epistaxis or other sites); specific testing for von Willebrand disease is indicated because the prothrombin time or partial thromboplastin time may be normal despite having a bleeding disorder. Nasal polyps or other intranasal growths may be associated with epistaxis. Recurrent, and often severe, nosebleeds may be the initial presenting symptom in **juvenile nasal angiofibroma,** which occurs in adolescent boys.

Table 377-1	Possible Causes of Epistaxis
Epistaxis digitorum (nose picking)	
Rhinitis (allergic or viral)	
Chronic sinusitis	
Foreign bodies	
Intranasal neoplasm or polyps	
Irritants (e.g., cigarette smoke)	
Septal deviation	
Septal perforation	
Trauma including child abuse	
Vascular malformation or telangiectasia (hereditary hemorrhage telangiectasia)	
Hemophilia	
von Willebrand disease	
Platelet dysfunction	
Thrombocytopenia	
Hypertension	
Leukemia	
Liver disease (e.g., cirrhosis)	
Medications (e.g., aspirin, anticoagulants, nonsteroidal antiinflammatory drugs, topical corticosteroids)	
Cocaine abuse

CLINICAL MANIFESTATIONS

Epistaxis usually occurs without warning, with blood flowing slowly but freely from 1 nostril or occasionally from both. In children with nasal lesions, bleeding might follow physical exercise. When bleeding occurs at night, the blood may be swallowed and become apparent only when the child vomits or passes blood in the stools. Posterior epistaxis can manifest as anterior nasal bleeding or, if bleeding is copious, the patient might vomit blood as the initial symptom.

TREATMENT

Most nosebleeds stop spontaneously in a few minutes. The nares should be compressed and the child kept as quiet as possible, in an upright position with the head tilted forward to avoid blood trickling back into the throat. Cold compresses applied to the nose can also help. If these measures do not stop the bleeding, local application of a solution of oxymetazoline (Afrin or Neo-Synephrine) (0.25-1%) may be useful. If bleeding persists, an anterior nasal pack may need to be inserted; if bleeding originates in the posterior nasal cavity, combined anterior and posterior packing is necessary. After bleeding is under control, and if a bleeding site is identified, its obliteration by cautery with silver nitrate may prevent further difficulties. Because the septal cartilage derives its nutrition from the overlying mucoperichondrium, only 1 side of the septum should be cauterized at a time to reduce the chance of a septal perforation. During the winter, or in a dry environment, a room humidifier, saline drops, and petrolatum (Vaseline) applied to the septum can help to prevent epistaxis. Antiseptic cream (e.g., mupirocin) significantly increases the proportion of children who have complete resolution of bleeding at 8 wk compared to no treatment. Ointments prevent infection, increase moisture, decrease bleeding, and are commonly used in clinical practice. However, the combination of silver nitrate cautery and antiseptic nasal cream is superior to antiseptic cream alone. Patients with severe epistaxis despite conservative medical measures should be considered for surgical ligation techniques or embolization. In patients with severe or repeated epistaxis, blood transfusions may be necessary. Otolaryngologic evaluation is indicated for these children and for those with bilateral bleeding or with hemorrhage that does not arise from the Kiesselbach plexus. Secondary epistaxis should be managed by identification of the cause, application of appropriate nasal therapy, and correct systemic medical management. Hematologic evaluation (for coagulopathy and anemia), along with nasal endoscopy and diagnostic imaging, may be needed to make a definitive diagnosis in cases of severe recurrent epistaxis. Replacement of deficient clotting factors may be required for patients who have an underlying hematologic disorder (see Chapter 476). Profuse unilateral epistaxis associated with a nasal mass in an adolescent boy near puberty might signal a **juvenile nasopharyngeal angiofibroma.** This unusual tumor has also been reported in a 2 yr old and in 30-40 yr olds, but the incidence peaks in adolescent and preadolescent boys. CT with contrast medium enhancement and MRI are part of the initial evaluation; arteriography, embolization, and extensive surgery may be needed.

Surgical intervention may also be needed for bleeding from the internal maxillary artery or other vessels that can cause bleeding in the posterior nasal cavity.

PREVENTION

The discouragement of nose picking, and attention to proper humidification of the bedroom during dry winter months helps to prevent many nosebleeds. Prompt attention to nasal infections and allergies is beneficial to nasal hygiene. Prompt cessation of nasal steroid sprays prevents ongoing bleeding.

Chapter 378

Nasal Polyps

Joseph Haddad Jr. and Sarah Keesecker

ETIOLOGY

Nasal polyps are benign pedunculated tumors formed from edematous, usually chronically inflamed nasal mucosa. They commonly arise from the ethmoidal sinus and occur in the middle meatus. Occasionally, they appear within the maxillary antrum and can extend to the nasopharynx (antrochoanal polyp).

It is estimated that between 0.2% and 1% of the population will develop nasal polyps at some time; the incidence of nasal polyps increases with age. Antrochoanal polyps represent only 4-6% of all nasal polyps in the general population but account for approximately one-third of polyps in the pediatric population. Large or multiple polyps can completely obstruct the nasal passage. The polyps originating from the ethmoidal sinus are usually smaller and multiple, as compared with the large and usually single antrochoanal polyp.

Cystic fibrosis (CF; see Chapter 403) is the most common childhood cause of nasal polyposis and up to 50% of CF patients experience obstructing nasal polyposis, which is rare in non-CF children. Therefore, CF should be suspected in any child younger than 12 yr old with nasal polyps, even in the absence of typical respiratory and digestive symptoms. Cystic fibrosis patients with homozygosity for F508del and other severe mutations appear to have an elevated risk of nasal polyps. Nasal polyposis is also associated with chronic sinusitis (see Chapter 380) and allergic rhinitis. In the *Samter triad*, nasal polyps are associated with aspirin sensitivity and asthma; this condition is rare.

CLINICAL MANIFESTATIONS

Obstruction of nasal passages is prominent, with associated hyponasal speech and mouth breathing. Profuse unilateral mucoid or mucopurulent rhinorrhea may also be present. An examination of the nasal passages shows glistening, gray, grape-like masses squeezed between the nasal turbinates and the septum.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Examination of the external nose and rhinoscopy is performed. Ethmoidal polyps can be readily distinguished from the well-vascularized turbinate tissue, which is pink or red; antrochoanal polyps may have a more fleshy appearance (Fig. 378-1). Antrochoanal polyps may prolapse into the nasopharynx; flexible nasopharyngoscopy can assist in

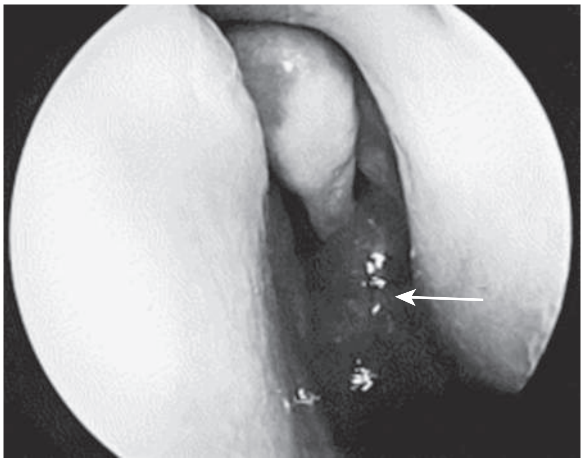

Figure 378-1 Antrochoanal polyp viewed endoscopically *(arrow). (From Basak S, Karaman CZ, Akdilli A, et al: Surgical approaches to antrochoanal polyps in children,* Int J Pediatr Otorhinolaryngol *46:197–205, 1998.)*

making this diagnosis. Prolonged presence of ethmoidal polyps in a child can widen the bridge of the nose and erode adjacent osseous structures. Tumors of the nose cause more local destruction and distortion of the anatomy. CT scan of the midface is key to diagnosis and planning for surgical treatment (Fig. 378-2).

TREATMENT

Local or systemic decongestants are not usually effective in shrinking the polyps, although they may provide symptomatic relief from the associated mucosal edema. Intranasal steroid sprays, and sometimes systemic steroids, can provide some shrinkage of nasal polyps with symptomatic relief and have proved useful in children with CF and adults with nasal polyps. Topical nasal steroid therapy, fluticasone, mometasone, and budesonide appears to result in nasal symptom improvement. Doxycycline (200 mg on the 1st day followed by 100 mg daily) has a significant effect on the size of nasal polyps, nasal symptoms, and mucosal and systemic markers of inflammation. Polyps should be removed surgically if complete obstruction, uncontrolled rhinorrhea, or deformity of the nose appears. If the underlying pathogenic mechanism cannot be eliminated (such as CF), the polyps may soon return. Functional endoscopic sinus surgery provides more complete polyp removal and treatment of other associated nasal disease; in some cases, this has reduced the need for frequent surgeries. Nasal steroid sprays should also be started preventively, once postsurgical healing occurs.

Antrochoanal polyps do not respond to medical measures and must be removed surgically. Because these types of polyps are not associated with any underlying disease process, the recurrence rate is much less than for other types of polyps.

Chapter 379

The Common Cold

E. Kathryn Miller and John V. Williams

The common cold is an acute viral infection of the upper respiratory tract in which the symptoms of rhinorrhea and nasal obstruction are prominent. Systemic symptoms and signs such as headache, myalgia, and fever are absent or mild. The common cold is frequently referred to as *infectious rhinitis* but may also include self-limited involvement of the sinus mucosa and is more correctly termed *rhinosinusitis.*

ETIOLOGY

The most common pathogens associated with the common cold are the more than 200 types of human rhinoviruses (see Chapter 263), but the syndrome can be caused by many different virus families (Table 379-1). Rhinoviruses are associated with more than 50% of colds in adults and children. In young children, other viral etiologies of the common cold include respiratory syncytial virus (RSV; see Chapter 260), human metapneumovirus (see Chapter 261), parainfluenza viruses (see Chapter 259), and adenoviruses (see Chapter 262). Common cold symptoms may also be caused by influenza viruses, nonpolio enteroviruses, and human coronaviruses. Many viruses that cause rhinitis are also associated with other symptoms and signs such as cough, wheezing, and fever.

EPIDEMIOLOGY

Colds occur year-round, but the incidence is greatest from the early fall until the late spring, reflecting the seasonal prevalence of the viral pathogens associated with cold symptoms. In the northern hemisphere, the highest incidence of rhinovirus infection occurs in the early fall (August-October) and in the late spring (April-May). The seasonal incidence for parainfluenza viruses usually peaks in the late fall and late spring and is highest between December and April for RSVs, influenza viruses, human metapneumoviruses, and coronaviruses. Adenoviruses are detected at a low prevalence throughout the cold season, and enteroviruses may also be detected during summer months or throughout the year.

Young children have an average of 6-8 colds per year, but 10-15% of children have at least 12 infections per year. The incidence of illness decreases with age, with 2-3 illnesses per year by adulthood. The incidence of infection is primarily a function of exposure to the virus. Children in out-of-home daycare centers during the 1st yr of life have 50% more colds than children cared for only at home. The difference in the incidence of illness between these groups of children decreases as the length of time spent in daycare increases, although the incidence of illness remains higher in the daycare group through at least the 1st 3 yr of life. When they begin primary school, children who attended daycare have less frequent colds than those who did not. Mannose-binding lectin deficiency with impaired innate immunity may be associated with an increased incidence of colds in children.

PATHOGENESIS

Viruses that cause the common cold are spread by 3 mechanisms: direct hand contact (self-inoculation of one's own nasal mucosa or conjunctivae after touching a contaminated person or object), inhalation of small-particle aerosols that are airborne from coughing, or deposition of large-particle aerosols that are expelled during a sneeze and land on nasal or conjunctival mucosa. Although the different common cold pathogens could be spread by any of these mechanisms, some routes of transmission appear to be more efficient than others for particular viruses. Studies of rhinoviruses and RSV indicate that direct contact is an efficient mechanism of transmission of these viruses, although transmission by large-particle aerosols can also occur. By contrast, influenza viruses and coronaviruses appear to be most efficiently spread by small-particle aerosols.

The respiratory viruses have evolved different mechanisms to avoid host defenses. Infections with rhinoviruses and adenoviruses result in the development of serotype-specific protective immunity. Repeated infections with these pathogens occur because there are a large number of distinct serotypes of each virus. Influenza viruses have the ability to change the antigens presented on the surface of the virus and thus behave as though there were multiple viral serotypes. The interaction of coronaviruses (see Chapter 264) with host immunity is not well defined, but it appears that multiple distinct strains of coronaviruses are capable of inducing at least short-term protective immunity. There are 4 types of parainfluenza viruses and 2 antigenic subgroups of RSV. In addition to antigenic diversity, many of these viruses are able to

Table 379-1 Pathogens Associated with the Common Cold

ASSOCIATION	PATHOGEN	RELATIVE FREQUENCY*	OTHER COMMON SYMPTOMS AND SIGNS
Agents primarily associated with the common cold	Human rhinoviruses	Frequent	Wheezing/bronchiolitis
	Coronaviruses	Occasional	
Agents primarily associated with other clinical syndromes that also cause common cold symptoms	Respiratory syncytial viruses	Occasional	Bronchiolitis in children <2 yr of age
	Human metapneumovirus	Occasional	Pneumonia and bronchiolitis
	Influenza viruses	Uncommon	Influenza, pneumonia, croup
	Parainfluenza viruses	Uncommon	Croup, bronchiolitis
	Adenoviruses	Uncommon	Pharyngoconjunctival fever (palpebral conjunctivitis, watery eye discharge, pharyngeal erythema)
	Enteroviruses	Uncommon	
	Coxsackievirus A		Herpangina (fever and ulcerated papules on posterior oropharynx
	Other nonpolio enteroviruses		Aseptic meningitis

*Relative frequency of colds caused by the agent.

reinfect the upper airway because mucosal immunoglobulin A induced by previous infection is short-lived, and the brief incubation period of these viruses allows the establishment of infection before immune memory responses. Although reinfection is not completely prevented by the adaptive host response to these viruses, the severity of illness is moderated by preexisting immunity.

Viral infection of the nasal epithelium can be associated with destruction of the epithelial lining, as with influenza viruses and adenoviruses, or there can be no apparent histologic damage, as with rhinoviruses and RSV. Regardless of the histopathologic findings, infection of the nasal epithelium is associated with an acute inflammatory response characterized by release of a variety of inflammatory cytokines and infiltration of the mucosa by inflammatory cells. This acute inflammatory response appears to be partially or largely responsible for many of the symptoms associated with the common cold. Viral shedding of most respiratory viruses peaks 3-5 days after inoculation, often coinciding with symptom onset; low levels of viral shedding may persist for up to 2 wk in the otherwise healthy host. Inflammation can obstruct the sinus ostia or eustachian tube, predisposing to bacterial sinusitis or otitis media.

The host immune system is responsible for most cold symptoms, rather than direct damage to the respiratory tract. Infected cells release cytokines, such as interleukin-8, that attract polymorphonuclear cells into the nasal submucosa and epithelium. Rhinoviruses also increase vascular permeability in the nasal submucosa, releasing albumin and bradykinin, which may contribute to symptoms.

Table 379-2 Conditions That Can Mimic the Common Cold

CONDITION	DIFFERENTIATING FEATURES
Allergic rhinitis	Prominent itching and sneezing, nasal eosinophils
Vasomotor rhinitis	May be triggered by irritants, weather changes, spicy foods, etc.
Rhinitis medicamentosa	History of nasal decongestant use
Foreign body	Unilateral, foul-smelling secretions Bloody nasal secretions
Sinusitis	Presence of fever, headache or facial pain, or periorbital edema or persistence of rhinorrhea or cough for longer than 14 days
Streptococcosis	Mucopurulent nasal discharge that excoriates the nares
Pertussis	Onset of persistent or severe paroxysmal cough
Congenital syphilis	Persistent rhinorrhea with onset in the 1st 3 mo of life

CLINICAL MANIFESTATIONS

Symptoms of the common cold vary by age and virus. In infants, fever and nasal discharge may predominate. Fever is uncommon in older children and adults. The onset of common cold symptoms typically occurs 1-3 days after viral infection. The first symptom noted is often sore or scratchy throat, followed closely by nasal obstruction and rhinorrhea. The sore throat usually resolves quickly and, by the 2nd and 3rd day of illness, nasal symptoms predominate. Cough is associated with two-thirds of colds in children and usually begins after the onset of nasal symptoms. Cough may persist for an additional 1-2 wk after resolution of other symptoms. Influenza viruses, RSVs, human metapneumoviruses, and adenoviruses are more likely than rhinoviruses or coronaviruses to be associated with fever and other constitutional symptoms. Other symptoms of a cold may include headache, hoarseness, irritability, difficulty sleeping, or decreased appetite. Vomiting and diarrhea are uncommon. The usual cold persists for approximately 1 wk, although 10% last for 2 wk.

The physical findings of the common cold are limited to the upper respiratory tract. Increased nasal secretion is usually obvious; a change in the color or consistency of the secretions is common during the course of the illness and does not indicate sinusitis or bacterial superinfection but may indicate accumulation of polymorphonuclear cells. Examination of the nasal cavity might reveal swollen, erythematous nasal turbinates, although this finding is nonspecific and of limited diagnostic value. Abnormal middle ear pressure is common during the course of a cold. Anterior cervical lymphadenopathy or conjunctival injection may also be noted on exam.

DIAGNOSIS

The most important task of the physician caring for a patient with a cold is to exclude other conditions that are potentially more serious or treatable. The differential diagnosis of the common cold includes noninfectious disorders as well as other upper respiratory tract infections (Table 379-2).

LABORATORY FINDINGS

Routine laboratory studies are not helpful for the diagnosis and management of the common cold. A nasal smear for eosinophils may be useful if allergic rhinitis is suspected (see Chapter 143). A predominance of polymorphonuclear cells in the nasal secretions is characteristic of uncomplicated colds and does not indicate bacterial superinfection. Self-limited radiographic abnormalities of the paranasal sinuses are common during an uncomplicated cold; imaging is not indicated for most children with simple rhinitis.

The viral pathogens associated with the common cold can be detected by polymerase chain reaction, culture, antigen detection, or

serologic methods. These studies are generally not indicated in patients with colds because a specific etiologic diagnosis is useful only when treatment with an antiviral agent is contemplated, such as for influenza viruses. Bacterial cultures or antigen detection are useful only when group A streptococcus (see Chapter 183) or *Bordetella pertussis* (see Chapter 197) is suspected. The isolation of other bacterial pathogens from nasopharyngeal specimens is not an indication of bacterial nasal infection and is not a specific predictor of the etiologic agent in sinusitis.

TREATMENT

The management of the common cold consists primarily of supportive care and anticipatory guidance as recommended by American Academy of Pediatrics and United Kingdom National Institute for Health and Clinical Excellence guidelines.

Antiviral Treatment

Specific antiviral therapy is not available for rhinovirus infections. Ribavirin, which is approved for treatment of severe RSV infections, has no role in the treatment of the common cold. The neuraminidase inhibitors oseltamivir and zanamivir have a modest effect on the duration of symptoms associated with influenza viral infections in children. Oseltamivir also reduces the frequency of influenza-associated otitis media. The difficulty of distinguishing influenza from other common cold pathogens and the necessity that therapy be started early in the illness (within 48 hr of onset of symptoms) to be beneficial are practical limitations to the use of these agents for mild upper respiratory tract infections. Antibacterial therapy is of no benefit in the treatment of the common cold and should be avoided to minimize possible adverse effects and the development of antibiotic resistance.

Supportive Care and Symptomatic Treatment

Supportive interventions are frequently recommended by providers. Maintaining adequate oral hydration may help to thin secretions and soothe respiratory mucosa. The common home remedy of ingesting warm fluids may soothe mucosa, increase nasal mucous flow, or loosen respiratory secretions. Topical nasal saline may temporarily remove secretions, and saline nasal irrigation may reduce symptoms. Cool, humidified air has not been well studied but may loosen nasal secretions; however, cool-mist humidifiers and vaporizers must be cleaned after each use. The World Health Organization suggests that neither steam nor cool-mist therapy be used in treatment of a cold.

The use of oral **nonprescription** therapies (often containing antihistamines, antitussives, and decongestants) for cold symptoms in children is controversial. Although some of these medications are effective in adults, no study demonstrates a significant effect in children, and there may be serious side effects. Young children cannot participate in the assessment of symptom severity, so studies of these treatments in children have generally been based on observations by parents or other observers, a method that is likely to be insensitive for detection of treatment effects. As a result of the lack of direct evidence for effectiveness and the potential for unwanted side effects, the American Academy of Pediatrics recommends that nonprescription cough and cold products **not** be used for infants and children younger than 6 yr of age. A decision whether to use these medications in older children must consider the likelihood of clinical benefit compared with the potential adverse effects of these drugs. The prominent or most bothersome symptoms of colds vary in the course of the illness. If symptomatic treatments are used, it is reasonable to target therapy to specific bothersome symptoms and care should be taken to ensure that caregivers understand the intended effect and can determine the proper dosage of the medications.

Zinc, given as oral lozenges to previously healthy patients, reduces the duration but not the severity of symptoms of a common cold if begun within 24 hr of symptoms. The function of the rhinovirus 3C protease, an essential enzyme for rhinovirus replication, is inhibited by zinc, but there has been no evidence of an antiviral effect of zinc in vivo. The effect of zinc on symptoms has been inconsistent, with some studies reporting dramatic treatment effects (in adults), whereas other studies find no benefit. Side effects are common and include decreased taste, bad taste, and nausea.

Fever

Fever is not usually associated with an uncomplicated common cold, and antipyretic treatment is generally not indicated.

Nasal Obstruction

Either topical or oral adrenergic agents may be used as nasal decongestants in older children and adults. Effective topical adrenergic agents such as xylometazoline, oxymetazoline, or phenylephrine are available as either intranasal drops or nasal sprays. Reduced-strength formulations of these medications are available for use in younger children, although they are not recommended for use in children younger than 6 yr old. Systemic absorption of the imidazolines (oxymetazoline, xylometazoline) has very rarely been associated with bradycardia, hypotension, and coma. Prolonged use of the topical adrenergic agents should be avoided to prevent the development of **rhinitis medicamentosa,** an apparent rebound effect that causes the sensation of nasal obstruction when the drug is discontinued. The oral adrenergic agents are less effective than the topical preparations and are occasionally associated with systemic effects such as central nervous system stimulation, hypertension, and palpitations. Aromatic vapors (such as menthol) for external rub may improve perception of nasal patency, but do not affect spirometry.

Saline nose drops (wash, irrigation) can improve nasal symptoms and may be used in all age groups.

Rhinorrhea

The first-generation antihistamines may reduce rhinorrhea by 25-30%. The effect of the antihistamines on rhinorrhea appears to be related to the anticholinergic rather than the antihistaminic properties of these drugs, and therefore the second-generation or “nonsedating” antihistamines have no effect on common cold symptoms. The major adverse effects associated with the use of the antihistamines are sedation or paradoxical hyperactivity. Overdose may be associated with respiratory depression or hallucinations. Rhinorrhea may also be treated with ipratropium bromide, a topical anticholinergic agent. This drug produces an effect comparable to the antihistamines but is not associated with sedation. The most common side effects of ipratropium are nasal irritation and bleeding.

Sore Throat

The sore throat associated with colds is generally not severe, but treatment with mild analgesics is occasionally indicated, particularly if there is associated myalgia or headache. The use of acetaminophen during rhinovirus infection is associated with suppression of neutralizing antibody responses, but this observation has no apparent clinical significance. Aspirin should not be given to children with respiratory infections because of the risk of Reye syndrome in children with influenza (see Chapter 361). **Nonsteroidal antiinflammatory drugs** are somewhat effective in relieving discomfort caused by a cold, but there is no clear evidence of their effect on respiratory symptoms. The balance of harm and benefits must be considered when using nonsteroidal antiinflammatory drugs for colds.

Cough

Cough suppression is generally not necessary in patients with colds. Cough in some patients appears to be from upper respiratory tract irritation associated with postnasal drip. Cough in these patients is most prominent during the time of greatest nasal symptoms, and treatment with a first-generation antihistamine may be helpful. Cough lozenges or hard candy may be temporarily effective and are unlikely to be harmful in children for whom they do not pose risk of aspiration (older than age 6 yr). **Honey** (5-10 mL in children ≥1 year old) has a modest effect on relieving nocturnal cough and is unlikely to be harmful in children older than 1 yr of age. Honey should be avoided in children younger than 1 yr of age because of the risk for botulism (see Chapter 210).

In some patients, cough may be a result of **virus-induced reactive airways disease**. These patients can have cough that persists for days to weeks after the acute illness and might benefit from bronchodilator or other therapy. Codeine or dextromethorphan hydrobromide has no effect on cough from colds and has potential enhanced toxicity. Expectorants such as guaifenesin are not effective antitussive agents. The combination of camphor, menthol, and eucalyptus oils may relieve nocturnal cough, but studies of their effectiveness are limited.

Ineffective Treatments

Vitamin C, guaifenesin, and inhalation of warm, humidified air are no more effective than placebo for the treatment of cold symptoms.

Echinacea is a popular herbal treatment for the common cold. Although echinacea extracts have biologic effects, echinacea is not effective as a common cold treatment. The lack of standardization of commercial products containing echinacea also presents a formidable obstacle to the rational evaluation or use of this therapy.

There is no evidence that the common cold or persistent acute purulent rhinitis of less than 10 days in duration benefits from antibiotics. In fact, there is evidence that antibiotics cause significant adverse effects when given for acute purulent rhinitis.

COMPLICATIONS

The most common complication of a cold is **acute otitis media (AOM;** see Chapter 640), which may be indicated by new-onset fever and earache after the 1st few days of cold symptoms. AOM is reported in 5-30% of children who have a cold, with the higher incidence occurring in young infants and in children cared for in a group daycare setting. Symptomatic treatment has no effect on the development of AOM, but treatment with oseltamivir might reduce the incidence of AOM in patients with influenza.

Sinusitis is another complication of the common cold (see Chapter 380). Self-limited sinus inflammation is a part of the pathophysiology of the common cold, but 0.5-2% of viral upper respiratory tract infections in adults, and 5-13% in children, are complicated by acute bacterial sinusitis. The differentiation of common cold symptoms from bacterial sinusitis may be difficult. The diagnosis of bacterial sinusitis should be considered if rhinorrhea or daytime cough persists without improvement for at least 10-14 days, if symptoms worsen over time, or if signs of more severe sinus involvement such as fever, facial pain, or facial swelling develop. There is no evidence that symptomatic treatment of the common cold alters the frequency of development of bacterial sinusitis. Bacterial pneumonia is an uncommon complication of the common cold.

Exacerbation of **asthma** is a relatively uncommon but potentially serious complication of colds. The majority of asthma exacerbations in children are associated with the common cold. There is no evidence that treatment of common cold symptoms prevents this complication; however, studies are underway in patients with underlying asthma to determine effectiveness of preventive or acute treatment at the onset of upper respiratory tract infection symptoms.

Although not a complication, another important consequence of the common cold is the inappropriate use of antibiotics for these illnesses and the associated contribution to the problem of increasing antibiotic resistance of pathogenic respiratory bacteria, as well as adverse effects from antibiotics.

PREVENTION

Chemoprophylaxis or immunoprophylaxis is generally not available for the common cold. Immunization or chemoprophylaxis against influenza can prevent colds caused by this pathogen; influenza is responsible for only a small proportion of all colds. Palivizumab is recommended to prevent RSV lower respiratory infection in high-risk infants but does not prevent upper respiratory infections from this virus. Vitamin C, garlic, or echinacea do not prevent the common cold. Vitamin C prophylaxis may shorten the duration of cold symptoms. Vitamin D deficiency is associated with increased risk of viral respiratory tract infection in some studies, nonetheless, vitamin D prophylaxis does not reduce incidence or severity of the common cold in adults; studies in children are lacking. Zinc sulfate taken for a minimum of 5 mo may reduce the rate of cold development. However, because of duration of use and adverse effects of bad taste and nausea, this is not a recommended prevention modality in children.

Hand-to-hand transmission of rhinoviruses followed by self-inoculation may be prevented by frequent hand washing and avoiding touching one's mouth, nose, and eyes. Some studies report the use of alcohol-based hand sanitizers and virucidal hand treatments were associated with decreased transmission. In the experimental setting, virucidal disinfectants or virucidal-impregnated tissues also reduce transmission of cold viruses; under natural conditions none of these interventions prevents common colds.

Chapter 380

Sinusitis

Diane E. Pappas and J. Owen Hendley

Sinusitis is a common illness of childhood and adolescence. There are 2 types of acute sinusitis: viral and bacterial, with significant acute and chronic morbidity as well as the potential for serious complications. The common cold produces a viral, self-limited rhinosinusitis (see Chapter 379). Approximately 0.5-2% of viral upper respiratory tract infections in children and adolescents are complicated by acute symptomatic bacterial sinusitis. Some children with underlying predisposing conditions have chronic sinus disease that does not appear to be infectious. The means for appropriate diagnosis and optimal treatment of sinusitis remain controversial.

Typically the **ethmoidal** and **maxillary** sinuses are present at birth, but only the ethmoidal sinuses are pneumatized. The maxillary sinuses are not pneumatized until 4 yr of age. The **sphenoidal** sinuses are present by 5 yr of age, whereas the **frontal sinuses** begin development at age 7-8 yr and are not completely developed until adolescence. The ostia draining the sinuses are narrow (1-3 mm) and drain into the ostiomeatal complex in the middle meatus. The **paranasal sinuses** are normally sterile, maintained by the mucociliary clearance system.

ETIOLOGY

The bacterial pathogens causing acute bacterial sinusitis in children and adolescents include *Streptococcus pneumoniae* (~30%; see Chapter 182), nontypeable *Haemophilus influenzae* (~20%; see Chapter 194), and *Moraxella catarrhalis* (~20%; see Chapter 196). Approximately 50% of *H. influenzae* and 100% of *M. catarrhalis* are β-lactamase positive. Approximately 25% of *S. pneumoniae* may be penicillin resistant. *Staphylococcus aureus,* other streptococci, and anaerobes are uncommon causes of acute bacterial sinusitis in children. Although *S. aureus* (see Chapter 181.1) is an uncommon pathogen for acute sinusitis in children, the increasing prevalence of methicillin-resistant *S. aureus* is a significant concern. *H. influenzae,* α- and β-hemolytic streptococci, *M. catarrhalis, S. pneumoniae,* and coagulase-negative staphylococci are commonly recovered from children with **chronic sinus disease.**

EPIDEMIOLOGY

Acute bacterial sinusitis can occur at any age. Predisposing conditions include viral upper respiratory tract infections (associated with out-of-home daycare or a school-age sibling), allergic rhinitis, and cigarette smoke exposure. Children with immune deficiencies particularly of antibody production (immunoglobulin IgG, IgG subclasses, IgA; see Chapter 124), cystic fibrosis (see Chapter 403), ciliary dysfunction (see Chapter 404), abnormalities of phagocyte function,

gastroesophageal reflux, anatomic defects (cleft palate), nasal polyps, cocaine abuse, and nasal foreign bodies (including nasogastric tubes) can develop chronic or recurrent sinus disease. Immunosuppression for bone marrow transplantation or malignancy with profound neutropenia and lymphopenia predisposes to severe fungal (aspergillus, mucor) sinusitis, often with intracranial extension. Patients with nasotracheal intubation or nasogastric tubes may have obstruction of the sinus ostia and develop sinusitis with the multiple-drug resistant organisms of the intensive care unit.

Acute sinusitis is defined by duration of <30 days; subacute by duration of 1-3 mo; and chronic by duration of longer than 3 mo.

PATHOGENESIS

Acute bacterial sinusitis typically follows a viral upper respiratory tract infection. Initially, the viral infection produces a viral rhinosinusitis; MRI evaluation of the paranasal sinuses demonstrates abnormalities (mucosal thickening, edema, inflammation) of the paranasal sinuses in 68% of healthy children in the normal course of the common cold. Nose blowing has been demonstrated to generate sufficient force to propel nasal secretions into the sinus cavities. Bacteria from the nasopharynx that enter the sinuses are normally cleared readily, but during viral rhinosinusitis, inflammation and edema can block sinus drainage and impair mucociliary clearance of bacteria. The growth conditions are favorable, and high titers of bacteria are produced.

CLINICAL MANIFESTATIONS

Children and adolescents with sinusitis can present with nonspecific complaints, including nasal congestion, purulent nasal discharge (unilateral or bilateral), fever, and cough. Less-common symptoms include bad breath (halitosis), a decreased sense of smell (hyposmia), and periorbital edema. Complaints of headache and facial pain are rare in children. Additional symptoms include maxillary tooth discomfort and pain or pressure exacerbated by bending forward. Physical examination might reveal erythema and swelling of the nasal mucosa with purulent nasal discharge. Sinus tenderness may be detectable in adolescents and adults. Transillumination reveals an opaque sinus that transmits light poorly.

Differentiating bacterial sinusitis from a cold may be difficult, but certain patterns suggestive of sinusitis have been identified. These include **persistence** of nasal congestion, rhinorrhea (of any quality) and daytime cough ≥10 days without improvement; **severe symptoms** of temperature ≥39°C (102°F) with purulent nasal discharge for 3 days or longer; and **worsening symptoms** either by recurrence of symptoms after an initial improvement or new symptoms of fever, nasal discharge and daytime cough.

DIAGNOSIS

The clinical diagnosis of acute bacterial sinusitis is based on history. Persistent symptoms of upper respiratory tract infection, including nasal discharge and cough, for longer than 10 days without improvement, or severe respiratory symptoms, including temperature of at least 39°C (102°F) and purulent nasal discharge for 3-4 consecutive days, suggest a complicating acute bacterial sinusitis. Bacteria are recovered from maxillary sinus aspirates in 70% of children with such persistent or severe symptoms studied. Children with chronic sinusitis have a history of persistent respiratory symptoms, including cough, nasal discharge, or nasal congestion, lasting longer than 90 days.

Sinus aspirate culture is the only accurate method of diagnosis but is not practical for routine use for immunocompetent patients. It may be a necessary procedure for immunosuppressed patients with suspected fungal sinusitis. In adults, *rigid nasal endoscopy* is a less-invasive method for obtaining culture material from the sinus but detects a great excess of positive cultures compared to aspirates. Findings on radiographic studies (sinus plain films, CT scans) including opacification, mucosal thickening, or presence of an air–fluid level are not diagnostic (Fig. 380-1) and are not recommended in otherwise healthy children. Such findings can confirm the presence of sinus inflammation but cannot be used to differentiate among viral, bacterial, or allergic causes of inflammation.

Given the nonspecific clinical picture, differential diagnostic considerations include viral upper respiratory tract infection, allergic rhinitis, nonallergic rhinitis, and nasal foreign body. Viral upper respiratory tract infections are characterized by clear and usually nonpurulent nasal discharge, cough, and initial fever; symptoms do not usually persist beyond 10-14 days, although a few children (10%) have persistent symptoms even at 14 days. Allergic rhinitis can be seasonal; evaluation of nasal secretions should reveal significant eosinophilia.

TREATMENT

It is unclear whether antimicrobial treatment of clinically diagnosed acute bacterial sinusitis offers any substantial benefit. A randomized, placebo-controlled trial comparing 14-day treatment of children with clinically diagnosed sinusitis with amoxicillin, amoxicillin-clavulanate, or placebo found that antimicrobial therapy did not affect resolution of symptoms, duration of symptoms, or days missed from school. A similar study in adults demonstrated improved symptoms at day 7 but not day 10 of treatment. Guidelines from the American Academy of Pediatrics recommend antimicrobial treatment for acute bacterial sinusitis with severe onset or a worsening course to promote resolution of symptoms and prevent suppurative complications, although 50-60% of children with acute bacterial sinusitis recover without antimicrobial therapy.

Initial therapy with amoxicillin (45 mg/kg/day divided bid) is adequate for the majority of children with uncomplicated mild to moderate severity acute bacterial sinusitis. Alternative treatments for the penicillin-allergic patient include cefdinir, cefuroxime axetil, cefpodoxime, or cefixime. In older children, levofloxacin is an alternative antibiotic. Azithromycin and trimethoprim-sulfamethoxazole are no longer indicated because of a high prevalence of antibiotic resistance. For children with risk factors (antibiotic treatment in the preceding 1-3 mo, daycare attendance, or age younger than 2 yr) for the presence of resistant bacterial species, and for children who fail to respond to initial therapy with amoxicillin within 72 hr, or with severe sinusitis, treatment with high-dose amoxicillin-clavulanate (80-90 mg/kg/day of amoxicillin) should be initiated. Ceftriaxone (50 mg/kg, IV or IM) may be given to children who are vomiting or who are at risk for poor compliance; it should be followed by a course of oral antibiotics. Failure to respond to these regimens necessitates referral to an otolaryngologist for further evaluation because maxillary sinus aspiration for culture and susceptibility testing may be necessary. The appropriate duration of therapy for sinusitis has yet to be determined; individualization of therapy is a reasonable approach, with treatment recommended for a minimum of 10 days or 7 days after resolution of symptoms (see Fig. 380-1).

Frontal sinusitis can rapidly progress to serious intracranial complications and necessitates initiation of parenteral ceftriaxone until substantial clinical improvement is achieved (Figs. 380-2 and 380-3). Treatment is then completed with oral antibiotic therapy.

The use of decongestants, antihistamines, mucolytics, and intranasal corticosteroids has not been adequately studied in children and is not recommended for the treatment of acute uncomplicated bacterial sinusitis. Likewise, saline nasal washes or nasal sprays can help to liquefy secretions and act as a mild vasoconstrictor, but the effects have not been systematically evaluated in children.

COMPLICATIONS

Because of the close proximity of the paranasal sinuses to the brain and eyes, serious orbital and/or intracranial complications can result from acute bacterial sinusitis and progress rapidly. Orbital complications, including *periorbital cellulitis* and *orbital cellulitis* (see Chapter 634) are most often secondary to acute bacterial ethmoiditis. Infection can spread directly through the lamina papyracea, the thin bone that forms the lateral wall of the ethmoidal sinus. Periorbital cellulitis produces erythema and swelling of the tissues surrounding the globe, whereas orbital cellulitis involves the intraorbital structures and produces proptosis, chemosis, decreased visual acuity, double vision and impaired extraocular movements, and eye pain (Fig. 380-4). Evaluation should include CT scan of the orbits and sinuses with ophthalmology and otolaryngology consultations. Treatment with intravenous antibiotics

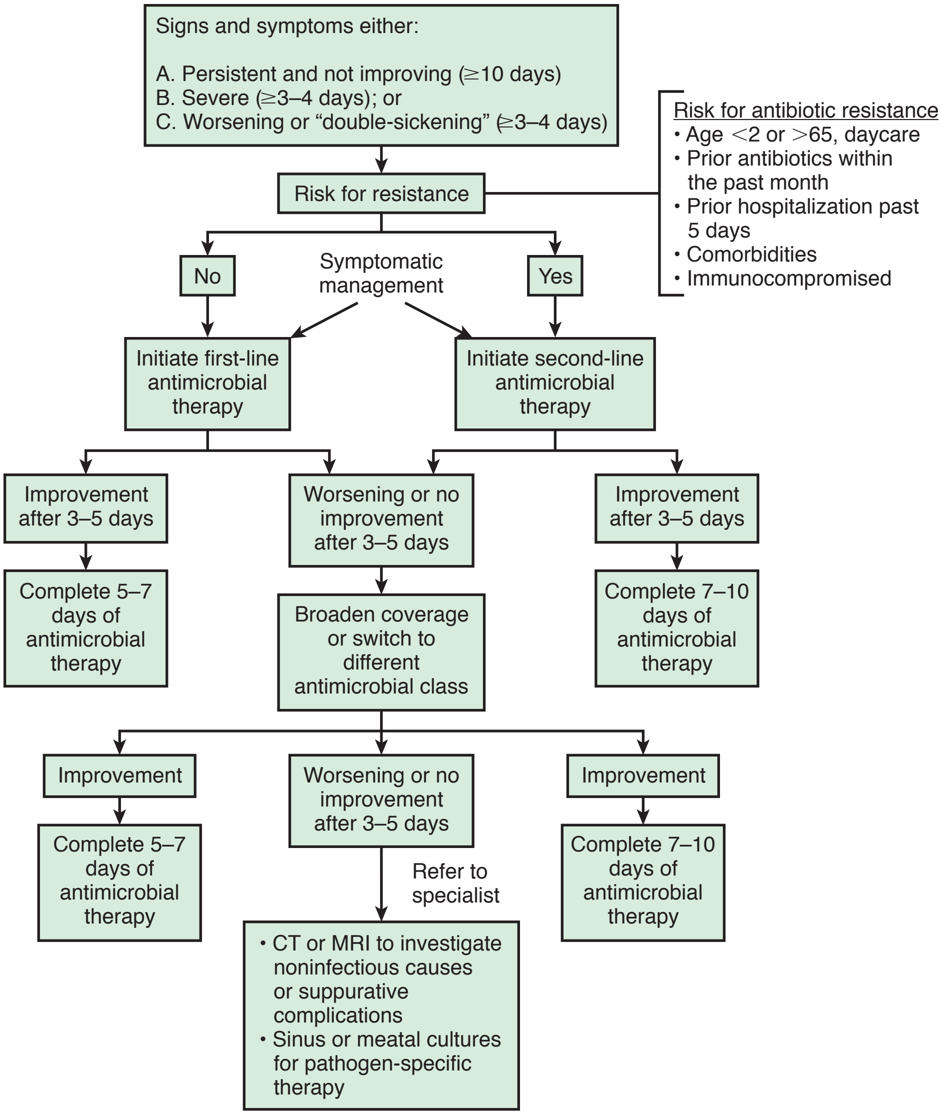

Figure 380-1 Algorithm for the management of acute bacterial rhinosinusitis. *(From Chow AW, Benninger MS, Brook I, et al: Infectious Diseases Society of America. IDSA clinical practice guideline for acute bacterial rhinosinusitis in children and adults.* Clin Infect Dis *54(8):e72–e112, 2012, Fig. 1.)*

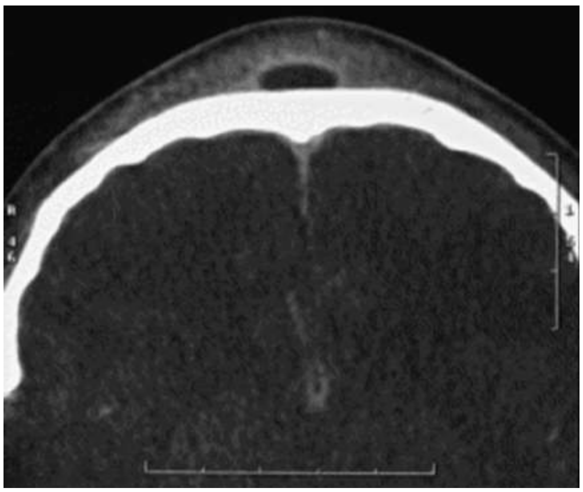

Figure 380-2 Axial plane contrast-enhanced CT scan of an 11 yr old boy with a frontal subperiosteal abscess secondary to acute frontal sinusitis. The CT scan demonstrates a ring-enhancing midline fluid density over the frontal bone. *(From Parikh SR, Brown SM: Image-guided frontal sinus surgery in children,* Operative Tech Otolaryngol Head Neck Surg *15:37–41, 2004.)*

should be initiated. Orbital cellulitis can require surgical drainage of the ethmoidal sinuses.

Intracranial complications can include epidural abscess, meningitis, cavernous sinus thrombosis, subdural empyema, and brain abscess (see Chapter 604). Children with altered mental status, nuchal rigidity, severe headache, focal neurologic findings, or signs of increased intracranial pressure (headache, vomiting) require immediate CT scan of the brain, orbits, and sinuses to evaluate for the presence of intracranial complications of acute bacterial sinusitis. Black children and males are at increased risk, but there is no evidence of increased risk due to socioeconomic status. Treatment with broad-spectrum intravenous antibiotics (usually cefotaxime or ceftriaxone combined with vancomycin) should be initiated immediately, pending culture and susceptibility results. In 50% the abscess is a polymicrobial infection. Abscesses can require surgical drainage. Other complications include osteomyelitis of the frontal bone (**Pott puffy tumor**), which is characterized by edema and swelling of the forehead (see Fig. 380-3), and **mucoceles,** which are chronic inflammatory lesions commonly located in the frontal sinuses that can expand, causing displacement of the eye with resultant diplopia. Surgical drainage is usually required.

PREVENTION

Prevention is best accomplished by frequent handwashing and avoiding persons with colds. Because acute bacterial sinusitis can complicate

influenza infection, prevention of influenza infection by yearly influenza vaccine will prevent some cases of complicating sinusitis. Immunization or chemoprophylaxis against influenza with oseltamivir or zanamivir may be useful for prevention of colds caused by this pathogen and the associated complications; influenza is responsible for only a small proportion of all colds.

Chapter 381

Acute Pharyngitis

Robert R. Tanz

Pharyngitis refers to inflammation of the pharynx, including erythema, edema, exudates, or an enanthem (ulcers, vesicles). Pharyngeal inflammation can be related to environmental exposures, such as tobacco smoke, air pollutants, and allergens; from contact with caustic substances, hot food, and liquids; and from infectious agents. The pharynx and mouth can be involved in various inflammatory conditions such as the periodic fever, aphthous stomatitis, pharyngitis, adenitis (PFAPA) syndrome, Kawasaki disease, inflammatory bowel disease, Stevens-Johnson syndrome, and systemic lupus erythematous. Noninfectious etiologies are typically evident from history and physical exam, but it can be more challenging to distinguish from among the numerous infectious causes of acute pharyngitis.

Acute infections of the upper respiratory tract account for a substantial number of visits to pediatricians and many feature sore throat as a symptom or evidence of pharyngitis on physical examination. The usual clinical task is to distinguish important, potentially serious, and treatable causes of acute pharyngitis from those that are self-limited and require no specific treatment or follow-up. Specifically, identifying patients who have **group A streptococcus** (GAS; *Streptococcus pyogenes;* see Chapter 183) pharyngitis and treating them with antibiotics forms the core of the management paradigm.

INFECTIOUS ETIOLOGIES

See Table 381-1.

Viruses

In North America and most industrialized countries GAS is the most important bacterial cause of acute pharyngitis, but viruses predominate as acute infectious causes of pharyngitis. Viral upper respiratory tract infections are typically spread by contact with oral or respiratory secretions and occur most commonly in fall, winter, and spring, that is, the "respiratory season." Important viruses that cause pharyngitis include influenza (see Chapter 258), parainfluenza (see Chapter 259), adenoviruses (see Chapter 262), coronaviruses (see Chapter 264), enteroviruses (see Chapter 250), rhinoviruses (see Chapter 263), respiratory

Table 381-1 Infectious Agents That Cause Pharyngitis

VIRUSES	BACTERIA
Adenovirus	*Streptococcus pyogenes* (Group A streptococcus)
Coronavirus	*Arcanobacterium haemolyticum*
Cytomegalovirus	*Fusobacterium necrophorum*
Epstein-Barr virus	*Corynebacterium diphtheriae*
Enteroviruses	*Neisseria gonorrhoeae*
Herpes simplex virus	Group C streptococci
Human immunodeficiency virus	Group G streptococci
Human metapneumovirus	*Francisella tularensis*
Influenza viruses	*Chlamydophila pneumoniae*
Measles virus	*Chlamydia trachomatis*
Parainfluenza viruses	*Mycoplasma pneumoniae*
Respiratory syncytial virus	
Rhinoviruses	

syncytial virus (see Chapter 260), cytomegalovirus (see Chapter 255), Epstein-Barr virus (see Chapter 254), herpes simplex virus (see Chapter 252), and human metapneumovirus (see Chapter 261). Most viral pharyngitis, except mononucleosis, is mild. Common nonspecific symptoms such as rhinorrhea and cough develop gradually before they become prominent. However, specific findings are sometimes helpful in identifying the infectious viral agent.

Gingivostomatitis and ulcerating vesicles throughout the anterior pharynx and on the lips are seen in primary oral herpes simplex virus infection. High fever and difficulty taking oral fluids are common. This infection can last for 14 days.

Discrete **papulovesicular** lesions or **ulcerations** in the posterior oropharynx, severe throat pain, and fever are characteristic of herpangina, caused by various enteroviruses. In hand-foot-mouth disease there are vesicles or ulcers throughout the oropharynx, vesicles on the palms and soles, and sometimes on the trunk and extremities; Coxsackie A16 is the most common agent, but Enterovirus 71 and Coxsackie A6 can also cause this syndrome. Enteroviral infections are most common in the summer.

Various adenoviruses cause pharyngitis. When there is concurrent **conjunctivitis** the syndrome is called *pharyngoconjunctival fever*. The pharyngitis tends to resolve within 7 days but conjunctivitis may persist for up to 14 days. Pharyngoconjunctival fever can be epidemic or sporadic; outbreaks have been associated with exposure in swimming pools.

Intense, diffuse pharyngeal erythema and Koplik spots, the pathognomonic enanthem, occur in advance of the characteristic rash of measles. Splenomegaly or hepatomegaly may be the clue to Epstein-Barr virus infectious mononucleosis in an adolescent with exudative tonsillitis. Primary infection with HIV can manifest as the acute retroviral syndrome, with non-exudative pharyngitis, fever, maculopapular rash, arthralgia, myalgia, adenopathy, and often a maculopapular rash.

Bacteria Other Than Group A Streptococcus

In addition to GAS, bacteria that cause pharyngitis include group C and group G streptococcus (see Chapter 185), *Arcanobacterium haemolyticum, Francisella tularensis* (see Chapter 206), *Neisseria gonorrhoeae* (see Chapter 192), *Mycoplasma pneumoniae* (see Chapter 223), *Chlamydophila* (formerly *Chlamydia*) *pneumoniae* (see Chapter 225), *Chlamydia trachomatis* (see Chapter 226), *Fusobacterium necrophorum*, and *Corynebacterium diphtheriae* (see Chapter 187). *Haemophilus influenzae* and *Streptococcus pneumoniae* may be cultured from the throats of children with pharyngitis, but their role in causing pharyngitis has not been established.

Group C and Group G streptococcus and *A. haemolyticum* pharyngitis have been diagnosed most commonly in adolescents and adults. They resemble group A β-hemolytic streptococcus (GABHS) pharyngitis and a scarlet fever–like rash may be present with *A. haemolyticum* infections.

F. necrophorum has been suggested to be a fairly common cause of pharyngitis in older adolescents and adults (15-30 yr old). Prevalence in studies has varied from 10-48% of patients with non-GABHS pharyngitis, but large surveillance studies have not been performed. *F. necrophorum* pharyngitis is associated with development of **Lemierre syndrome**, internal jugular vein septic thrombophlebitis. Approximately 80% of cases of Lemierre syndrome are caused by this bacterium. Patients present initially with fever, sore throat, exudative pharyngitis, and/or peritonsillar abscess. The symptoms may persist, neck pain and swelling develop, and the patient appears toxic. Septic shock may ensue along with metastatic complications from septic emboli that can involve the lungs, bones and joints, central nervous system, abdominal organs, and soft tissues. The case fatality rate is 4-9%.

Gonococcal pharyngeal infections are usually asymptomatic but can cause acute pharyngitis with fever and cervical lymphadenitis. Young children with proven gonococcal disease should be evaluated for sexual abuse.

Diphtheria is extremely rare in most developed countries thanks to extensive immunization with diphtheria toxoid. However, it remains endemic in many areas of the world, including the former Soviet bloc countries, Africa, Asia, the Middle East, and Latin America. It can be considered in patients with recent travel to or from these areas and in unimmunized patients. Key physical findings are bull neck (extreme neck swelling) and a gray pharyngeal pseudomembrane that can cause respiratory obstruction.

Ingestion of water, milk, or undercooked meat contaminated by *F. tularensis* can lead to oropharyngeal tularemia. Severe throat pain, tonsillitis, cervical adenitis, oral ulcerations, and a pseudomembrane (as in diphtheria) may be present. *M. pneumoniae* and *C. pneumonia*e cause pharyngitis, but other upper and lower respiratory infections are more important and more readily recognized. Development of a severe or persistent cough subsequent to pharyngitis may be the clue to infection with one of these organisms.

Group A Streptococcus

Streptococcal pharyngitis is relatively uncommon before 2-3 yr of age, is quite common among children 5-15 yr old, and declines in frequency in late adolescence and adulthood. Illness occurs throughout the year but is most prevalent in winter and spring. It is readily spread among siblings and schoolmates. GAS causes 15-30% of pharyngitis in school-age children.

Colonization of the pharynx by GAS can result in either asymptomatic carriage or acute infection. After an incubation period of 2-5 days, pharyngeal infection with GAS classically presents as rapid onset of significant sore throat and fever. The pharynx is red, the tonsils are enlarged and often covered with a white, grayish, or yellow exudate that may be blood-tinged. There may be petechiae or "doughnut" lesions on the soft palate and posterior pharynx and the uvula may be red and swollen. The surface of the tongue can resemble a strawberry when the papillae are inflamed and prominent ("strawberry tongue"). Initially, the tongue is often coated white, and with the swollen papillae it is called a "white strawberry tongue." When the white coating is gone after a few days, the tongue is often quite red, and is called a "red strawberry tongue." Enlarged and tender anterior cervical lymph nodes are frequently present. Headache, abdominal pain, and vomiting are frequently associated with the infection, but in the absence of clinical pharyngitis, gastrointestinal signs and symptoms should not be attributed to GAS. Ear pain is a frequent complaint but the tympanic membranes are usually normal. Diarrhea, cough, coryza, ulcerations, croup/laryngitis/hoarseness, and conjunctivitis are not associated with GAS pharyngitis and increase the likelihood of a viral etiology.

Patients infected with GAS that produce streptococcal pyrogenic exotoxin A, B, or C may demonstrate the fine red, papular ("sandpaper") rash of scarlet fever. It begins on the face and then becomes generalized. The cheeks are red and the area around the mouth is more pale, giving the appearance of circumoral pallor. The rash blanches with pressure and it may be more intense in skin creases, especially in the antecubital fossae, axillae, and inguinal creases (Pastia's lines or Pastia's sign). Pastia's lines are sometimes petechial or slightly hemorrhagic.

Capillary fragility can cause petechiae distal to a tourniquet or constriction from clothing, a positive tourniquet test or Rumpel-Leeds phenomenon. Erythema fades in a few days and when the rash resolves it typically peels like a mild sunburn. Sometimes there is sheet-like desquamation around the free margins of the finger nails. Streptococcal pyrogenic exotoxin A, encoded by the gene *spe A*, is the exotoxin most commonly associated with scarlet fever.

The M protein is an important GAS virulence factor that facilitates resistance to phagocytosis. The M protein is encoded by the *emm* gene and determines the M type (or *emm* type). Molecular methods have identified more than 200 *emm* genes (*emm* types). The M protein is immunogenic; an individual can experience multiple episodes of GAS pharyngitis in a lifetime because natural immunity is M type-specific. Numerous GAS M types can circulate in a community simultaneously and they enter and leave communities unpredictably and for unknown reasons.

DIAGNOSIS

The clinical presentations of streptococcal and viral pharyngitis often overlap. In particular, the pharyngitis of mononucleosis can be difficult to distinguish from GAS pharyngitis. Physicians relying solely on clinical judgment often overestimate the likelihood of a streptococcal etiology. Various clinical scoring systems have been described to assist in identifying patients who are likely to have GAS pharyngitis. Criteria developed for adults and modified for children by McIsaac give 1 point for each of the following criteria: history of temperature >38°C (100.4°F); absence of cough; tender anterior cervical adenopathy; tonsillar swelling or exudates; and age 3-14 yr. It subtracts a point for age ≥45 yr. At best, a McIsaac score ≥4 is associated with a positive laboratory test for GAS in less than 70% of children with pharyngitis (Table 381-2), so it, too, overestimates the likelihood of GAS. Consequently, laboratory testing is essential for accurate diagnosis. Clinical findings and/or scoring systems can best be used to assist the clinician in identifying patients in need of testing. Streptococcal antibody tests are not useful in assessing patients with acute pharyngitis.

Throat culture and **rapid antigen-detection tests** (RADTs) are the diagnostic tests for GAS available in routine clinical care. Throat culture remains the “gold standard” for diagnosing streptococcal pharyngitis. There are both false-negative cultures as a consequence of sampling errors or prior antibiotic treatment and false-positive cultures as a consequence of misidentification of other bacteria as GAS. Some laboratories prefer nucleic acid testing that is specific for GAS and no longer use culture to confirm the diagnosis. A child who is chronically colonized with GAS (streptococcal carrier) can have a positive culture if it is obtained when the child is evaluated for pharyngitis that is actually caused by a viral infection.

Streptococcal RADTs detect the group A carbohydrate of GAS. They are used by the vast majority of office-based pediatricians. All RADTs have very high specificity, generally ≥95%, so when a RADT is positive it is assumed to be accurate and throat culture is unnecessary. Because RADTs are generally less sensitive than culture, confirming a negative rapid test with a throat culture is recommended. RADTs and throat culture exhibit spectrum bias: They are more sensitive when the pretest probability of GAS is high (signs and symptoms are typical of GAS infection) and less sensitive when the pretest probability is low. Avoidance of testing when patients have signs and symptoms more suggestive of a viral infection is recommended.

Testing for bacteria other than GAS is performed infrequently, and should be reserved for patients with persistent symptoms and symptoms suggestive of a specific non-GAS bacterial pharyngitis, for example, when there is concern for gonococcal infection or sexual abuse. Special culture media and a prolonged incubation are required to detect *A. haemolyticum*. Viral cultures are often unavailable and are generally too expensive and slow to be clinically useful. Polymerase chain reaction is more rapid and multiplex polymerase chain reaction testing for respiratory pathogens can identify a variety of viral and bacterial agents within a few hours. This may be useful in determining the isolation needs of hospitalized patients, assisting in patient prognosis, and epidemiology, but in the absence of specific treatment for most viral infections such testing is usually not necessary. A complete blood cell count showing many atypical lymphocytes and a positive mononucleosis slide agglutination test can help to confirm a clinical diagnosis of Epstein-Barr virus infectious mononucleosis.

TREATMENT

Specific therapy is unavailable for most viral pharyngitis. However, nonspecific, symptomatic therapy can be an important part of the overall treatment plan. An oral antipyretic/analgesic agent (acetaminophen or ibuprofen) can relieve fever and sore throat pain. Anesthetic sprays and lozenges (often containing benzocaine, phenol, or menthol) can provide local relief in children who are developmentally appropriate to use them. Systemic corticosteroids are sometimes used in children who have evidence of upper airway compromise due to mononucleosis. Although corticosteroids are used fairly commonly in adults with pharyngitis, large scale studies capable of providing safety and efficacy data are lacking in children. *Corticosteroids cannot be recommended for treatment of most pediatric pharyngitis.*

Antibiotic therapy of bacterial pharyngitis depends on the organism identified. On the basis of in vitro susceptibility data, oral penicillin is often suggested for patients with group C streptococcal isolates and oral erythromycin is recommended for patients with *A. haemolyticum*, but the clinical benefit of such treatment is uncertain.

Most untreated episodes of GAS pharyngitis resolve uneventfully within 5 days, but early antibiotic therapy hastens clinical recovery by 12-24 hr. The primary benefit and intent of antibiotic treatment is the prevention of acute rheumatic fever (ARF); it is highly effective when started within 9 days of onset of illness. Antibiotic therapy does not prevent acute poststreptococcal glomerulonephritis (APSGN). Antibiotic therapy should not be delayed for children with symptomatic pharyngitis and a positive GAS RADT or throat culture. Presumptive antibiotic treatment can be started when there is a clinical diagnosis of scarlet fever, a symptomatic child has a household contact with

Table 381-2 Positive Predictive Value of McIsaac Score in Children in Clinical Studies*

SCORE	McISAAC, 2004 (N = 454)	EDMONSON, 2005 (N = 1184)	TANZ, 2009 (N = 1848)	FINE, 2012 (N = 64,789)
0	—	—	7%	17%
1	—	0.5%	19%	23%
2	20.5%	8.9%	20%	34%
3	27.5%	42.4%	29%	50%
≥4	67.8%	48.2%	49%	68%
GAS prevalence	34%	38%	30%	37%

*One point is given for each of the following criteria: history of temperature >38°C (100.4°F); absence of cough; tender anterior cervical adenopathy; tonsillar swelling or exudates; and age 3-14 yr. Note that the Centor score lacks only the age criterion. Positive predictive value refers to the proportion of patients with documented GAS by rapid antigen-detection test and/or throat culture.

Table 381-3 Recommended Treatment for Acute Streptococcal Pharyngitis

MOST PATIENTS				
	WEIGHT <27 kg	**WEIGHT ≥27 kg**	**ROUTE**	**DURATION**
Amoxicillin	50 mg/kg once daily (maximum 1000 mg)		Oral	10 days
Penicillin V	250 mg bid	500 mg bid	Oral	10 days
Benzathine penicillin G	600,000 units	1.2 million units	IM	Once
Benzathine penicillin G + procaine penicillin G	900,000 units + 300,000 units	900,000 units + 300,000 units	IM	Once

PENICILLIN-ALLERGIC PATIENTS			
	ORAL DOSE	**FREQUENCY**	**DURATION**
Cephalosporins*	Varies with agent chosen		10 days
Erythromycin			
Ethylsuccinate	40 mg/kg/day up to 1000 mg/day	bid	10 days
Estolate	20-40 mg/kg/day up to 1000 mg/day	bid	10 days
Clarithromycin	15 mg/kg/day up to 500 mg/day	bid	10 days
Azithromycin†	12 mg/kg day 1; 6 mg/kg days 2-5	qd	5 days
Clindamycin	20 mg/kg/day up to 1.8 g/day	tid	10 days

*First-generation cephalosporins are preferred; dosage and frequency vary among agents. Do not use in patients with history of immediate (anaphylactic) hypersensitivity to penicillin or other β-lactam antibiotics.
†Maximum dose is 500 mg the 1st day, 250 mg subsequent days.

documented streptococcal pharyngitis, or a history of ARF in the patient or a family member, but a diagnostic test should be performed to confirm the presence of GAS.

A variety of antimicrobial agents are effective for GAS pharyngitis (Table 381-3). Group A streptococci are universally susceptible to penicillin and all other β-lactam antibiotics. Penicillin is inexpensive, has a narrow spectrum of activity, and few adverse effects. Amoxicillin is preferred for children because of taste, availability as chewable tablets and liquid, and convenience of once-daily dosing. The duration of oral penicillin and amoxicillin therapy is 10 days. A single intramuscular dose of benzathine penicillin or a benzathine-procaine penicillin G combination is effective and ensures compliance. Follow-up testing for GAS is unnecessary after completion of therapy and is not recommended unless symptoms recur.

Patients allergic to penicillin can be treated with a 10-day course of a narrow-spectrum (first-generation) cephalosporin (cephalexin or cefadroxil) if the previous reaction to penicillin was not an immediate, type I hypersensitivity reaction. Most often, penicillin-allergic patients are treated for 10 days with erythromycin, clarithromycin, or clindamycin, or for 5 days with azithromycin.

The increased use of macrolides and related antibiotics for a variety of infections, especially the azalide, azithromycin, is associated with increased rates of resistance to these drugs among GAS in many countries. Approximately 5% of GAS in the United States and more than 10% in Canada are macrolide-resistant (macrolide resistance includes azalide resistance), but there is considerable local variation in both countries. Some macrolide-resistant GAS isolates are also resistant to clindamycin. Although not a major hindrance for treatment of pharyngitis, clindamycin resistance may be important in management of invasive GAS infections. Use of these antibiotics should be restricted to patients who cannot safely receive a β–lactam drug for GAS pharyngitis. Tetracyclines, fluoroquinolones, or sulfonamides should ***not*** be used to treat GAS pharyngitis.

CHRONIC GROUP A STREPTOCOCCUS CARRIERS

Patients who continue to harbor GAS in the pharynx despite appropriate antibiotic therapy are streptococcal carriers. They have little or no evidence of an immune response to the organism. The pathogenesis of chronic carriage is not known. Carriage generally poses little risk to patients and their contacts, but it can confound testing in subsequent episodes of sore throat. Patients with repeated test-positive pharyngitis create anxiety among their families and physicians. It is usually unnecessary to attempt to eliminate chronic carriage. Instead, evaluation and treatment of pharyngitis should be undertaken without regard for chronic carriage, treating test-positive patients in routine fashion and avoiding antibiotics in patients who have negative tests. Expert opinion suggests that eradication might be attempted in select circumstances: a community outbreak of ARF or APSGN; personal or family history of ARF; an outbreak of GAS pharyngitis in a closed or semiclosed community, nursing home or healthcare facility; repeated episodes of symptomatic GAS pharyngitis in a family with "ping pong" spread among family members despite adequate therapy; when tonsillectomy is being considered because of chronic carriage or recurrent streptococcal pharyngitis; and extreme, unmanageable anxiety related to GAS carriage ("streptophobia") among family members. Clindamycin given by mouth for 10 days is effective therapy (20 mg/kg/day divided in 3 doses; adult dose 150-450 mg tid). Amoxicillin-clavulanate (40 mg amoxicillin/kg/day up to 2000 mg amoxicillin/day divided tid for 10 days) and 4 days of oral rifampin plus either intramuscular benzathine penicillin given once or oral penicillin given for 10 days have also been used.

RECURRENT PHARYNGITIS

True recurrent GAS pharyngitis can occur for several reasons: reinfection with the same M type if type-specific antibody has not developed; poor compliance with oral antibiotic therapy; macrolide resistance if a macrolide was used for treatment; and infection with a new M type. Unfortunately, determining the GAS M type in an acute infection is not available to the clinician. Treatment with intramuscular benzathine penicillin eliminates nonadherence to therapy. Apparent recurrences can represent pharyngitis of another cause in the presence of streptococcal carriage. Chronic GAS carriage is particularly likely if the illnesses are mild and otherwise atypical for GAS pharyngitis. *Undocumented histories of recurrent pharyngitis are an inadequate basis for recommending tonsillectomy.*

Tonsillectomy may lower the incidence of pharyngitis for 1-2 yr among children with frequent episodes of documented pharyngitis (≥7 episodes in the previous year or ≥5 in each of the preceding 2 yr, or ≥3 in each of the previous 3 yr). However, the frequency of pharyngitis (GAS and non-GAS) generally declines over time. By 2 yr posttonsillectomy the incidence of pharyngitis in severely affected children is

similar among those who have tonsillectomy and those who do not. Few children are so severely affected and the limited clinical benefit of tonsillectomy for most must be balanced against the risks of anesthesia and surgery.

Recurrent GAS pharyngitis is rarely, if ever, a sign of an immune disorder. However, recurrent pharyngitis can be part of a recurrent fever or autoinflammatory syndrome such as PFAPA syndrome. Prolonged pharyngitis (>1 wk) can occur in infectious mononucleosis and Lemierre syndrome, but it also suggests the possibility of another disorder such as neutropenia, a recurrent fever syndrome, or an autoimmune disease such as systemic lupus or inflammatory bowel disease. In such instances, pharyngitis would be one of a number of clinical findings that together should suggest the underlying diagnosis.

COMPLICATIONS AND PROGNOSIS

Viral respiratory tract infections can predispose to bacterial middle ear infections and bacterial sinusitis. The complications of GAS pharyngitis include local suppurative complications, such as parapharyngeal abscess, and subsequent nonsuppurative illnesses, such as ARF, APSGN, poststreptococcal reactive arthritis, and possibly PANDAS (pediatric autoimmune neuropsychiatric disorders associated with *S. pyogenes*) or CANS (childhood acute neuropsychiatric symptoms).

PREVENTION

A variety of GAS vaccines are being developed. A recombinant multivalent M-type vaccine uses the terminal portions of various M proteins to take advantage of their immunogenicity. Other vaccines are based on more conserved GAS epitopes in order to avoid the necessity of matching the vaccine with the M types prevalent in a community or target population. None of the investigational GAS vaccines are near licensing for use. Antimicrobial prophylaxis with daily oral penicillin prevents recurrent GAS infections but is recommended only to prevent recurrences of ARF.

Chapter 382

Retropharyngeal Abscess, Lateral Pharyngeal (Parapharyngeal) Abscess, and Peritonsillar Cellulitis/Abscess

Diane E. Pappas and J. Owen Hendley

The *retropharyngeal* and the *lateral pharyngeal lymph nodes* that drain the mucosal surfaces of the upper airway and digestive tracts are located in the neck within the *retropharyngeal space* (located between the pharynx and the cervical vertebrae and extending down into the superior mediastinum) and the *lateral pharyngeal space* (bounded by the pharynx medially, the carotid sheath posteriorly, and the muscles of the styloid process laterally). The lymph nodes in these deep neck spaces communicate with each other, allowing bacteria from either cellulitis or node abscess to spread to other nodes. Infection of the nodes usually occurs as a result of extension from a localized infection of the oropharynx. A **retropharyngeal abscess** can also result from penetrating trauma to the oropharynx, dental infection, and vertebral osteomyelitis. Once infected, the nodes may progress through 3 stages: *cellulitis, phlegmon,* and *abscess.* Infection in the retropharyngeal and lateral pharyngeal spaces can result in airway compromise or posterior mediastinitis, making timely diagnosis important.

RETROPHARYNGEAL AND LATERAL PHARYNGEAL ABSCESS

Retropharyngeal abscess occurs most commonly in children younger than 3-4 yr of age; as the retropharyngeal nodes involute after 5 yr of age, infection in older children and adults is much less common.

Boys are affected more often than girls and approximately two-thirds of patients have a history of recent ear, nose, or throat infection.

Clinical manifestations of retropharyngeal abscess are nonspecific and include fever, irritability, decreased oral intake, and drooling. Neck stiffness, torticollis, and refusal to move the neck may also be present. The verbal child might complain of sore throat and neck pain. Other signs can include muffled voice, stridor, respiratory distress, or even obstructive sleep apnea. Physical examination can reveal bulging of the posterior pharyngeal wall, although this is present in <50% of infants with retropharyngeal abscess. Cervical lymphadenopathy may also be present. Lateral pharyngeal abscess commonly presents as fever, dysphagia, and a prominent bulge of the lateral pharyngeal wall, sometimes with medial displacement of the tonsil.

The differential diagnosis includes acute epiglottitis and foreign body aspiration. In the young child with limited neck mobility, meningitis must also be considered. Other possibilities include lymphoma, hematoma, and vertebral osteomyelitis.

Incision and drainage and culture of an abscessed node provides the definitive diagnosis, but CT can be useful in identifying the presence of a retropharyngeal, lateral pharyngeal, or parapharyngeal abscess (Figs. 382-1 and 382-2). With CT scans, deep neck infections can be accurately identified and localized, but CT accurately identifies abscess formation in only 63% of patients. Soft-tissue neck films taken during inspiration with the neck extended might show increased width or an air–fluid level in the retropharyngeal space. CT with contrast medium enhancement can reveal central lucency, ring enhancement, or scalloping of the walls of a lymph node. Scalloping of the abscess wall is thought to be a late finding and predicts abscess formation.

Retropharyngeal and lateral pharyngeal infections are most often polymicrobial; the usual pathogens include group A streptococcus (see Chapter 183), oropharyngeal anaerobic bacteria (see Chapter 213), and *Staphylococcus aureus* (see Chapter 181.1). In children younger than age 2 yr, there has been an increase in the incidence of retropharyngeal abscess, particularly with *S. aureus,* including methicillin-resistant strains. Mediastinitis may be identified on CT in some of these patients. Other pathogens can include *Haemophilus influenzae, Klebsiella,* and *Mycobacterium avium-intracellulare.*

Treatment options include intravenous antibiotics with or without surgical drainage. A third-generation cephalosporin combined with ampicillin-sulbactam or clindamycin to provide anaerobic coverage is effective. The increasing prevalence of methicillin-resistant *S. aureus* can influence empiric antibiotic therapy. Studies show that >50% of children with retropharyngeal or lateral pharyngeal abscess as identified by CT can be successfully treated without surgical drainage. Drainage is necessary in the patient with respiratory distress or failure to improve with intravenous antibiotic treatment. The optimal duration of treatment is unknown, but therapy for several days with intravenous antibiotics until the patient has begun to improve followed by a course of oral antibiotic is typically used.

Complications of retropharyngeal or lateral pharyngeal abscess include significant upper airway obstruction, rupture leading to aspiration pneumonia, and extension to the mediastinum. Thrombophlebitis of the internal jugular vein and erosion of the carotid artery sheath can also occur.

An uncommon but characteristic infection of the parapharyngeal space is **Lemierre disease,** in which infection from the oropharynx extends to cause septic thrombophlebitis of the internal jugular vein

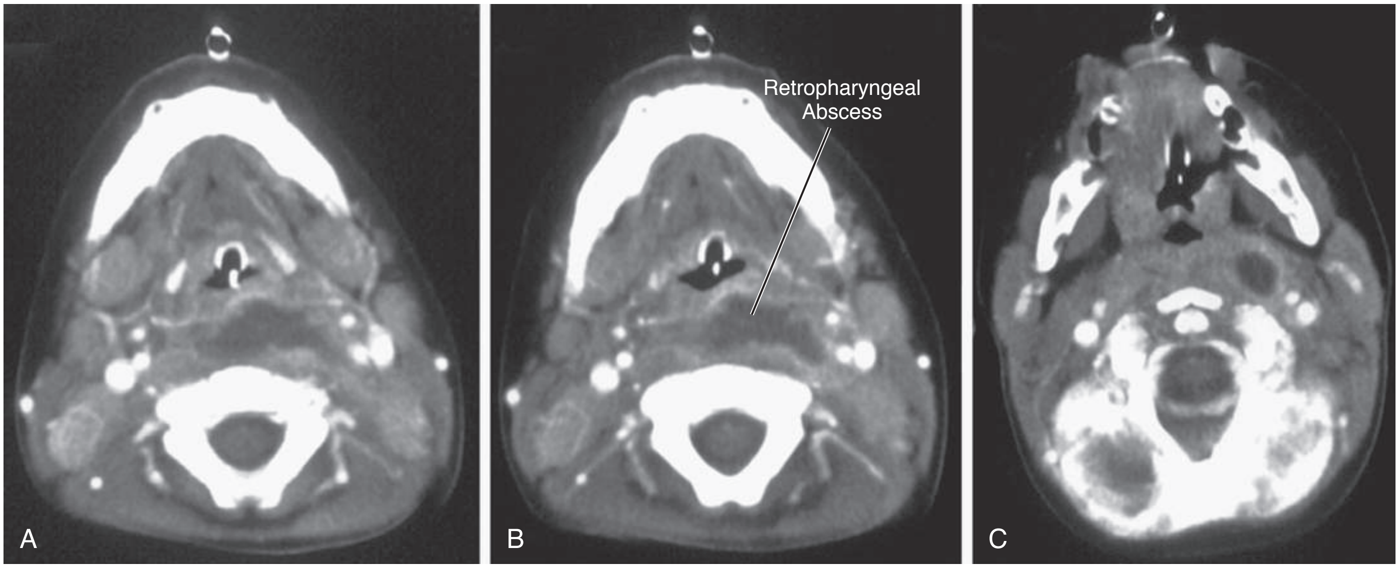

Figure 382-1 CT of retropharyngeal abscess. **A,** CT image at level of epiglottis. **B,** Sequential CT slice exhibiting ring-enhancing lesion. **C,** Further sequential CT slice demonstrating inferior extent of lesion. *(From Philpott CM, Selvadurai D, Banerjee AR: Paediatric retropharyngeal abscess,* J Laryngol Otol *118:925, 2004.)*

and embolic abscesses in the lungs (Fig. 382-3). The causative pathogen is *Fusobacterium necrophorum,* an anaerobic bacterial constituent of the oropharyngeal flora. The typical presentation is that of a previously healthy adolescent or young adult with a history of recent pharyngitis who becomes acutely ill with fever, hypoxia, tachypnea, and respiratory distress. Chest radiography demonstrates multiple cavitary nodules, often bilateral and often accompanied by pleural effusion. Blood culture may be positive. Treatment involves prolonged intravenous antibiotic therapy with penicillin or cefoxitin; surgical drainage of extrapulmonary metastatic abscesses may be necessary (see Chapters 381 and 383).

PERITONSILLAR CELLULITIS AND/OR ABSCESS

Peritonsillar cellulitis and/or abscess, which is relatively common compared to the deep neck infections, is caused by bacterial invasion through the capsule of the tonsil, leading to cellulitis and/or abscess formation in the surrounding tissues. The typical patient with a peritonsillar abscess is an adolescent with a recent history of acute pharyngotonsillitis. Clinical manifestations include sore throat, fever, trismus, and dysphagia. Physical examination reveals an asymmetric tonsillar bulge with displacement of the uvula. An asymmetric tonsillar bulge is diagnostic, but it may be poorly visualized because of trismus. CT is helpful for revealing the abscess. Group A streptococci and mixed oropharyngeal anaerobes are the most common pathogens, with more than 4 bacterial isolates per abscess typically recovered by needle aspiration.

Treatment includes surgical drainage and antibiotic therapy effective against group A streptococci and anaerobes. Surgical drainage may be accomplished through needle aspiration, incision and drainage, or tonsillectomy. Needle aspiration can involve aspiration of the superior, middle, and inferior aspects of the tonsil to locate the abscess. Intraoral ultrasound can be used to diagnose and guide needle aspiration of a peritonsillar abscess. General anesthesia may be required for the uncooperative patient. Approximately 95% of peritonsillar abscesses resolve after needle aspiration and antibiotic therapy. A small percentage of these patients require a repeat needle aspiration. The 5% with infections that fail to resolve after needle aspiration require incision and drainage. Tonsillectomy should be considered if there is failure to improve within 24 hr of antibiotic therapy and needle aspiration,

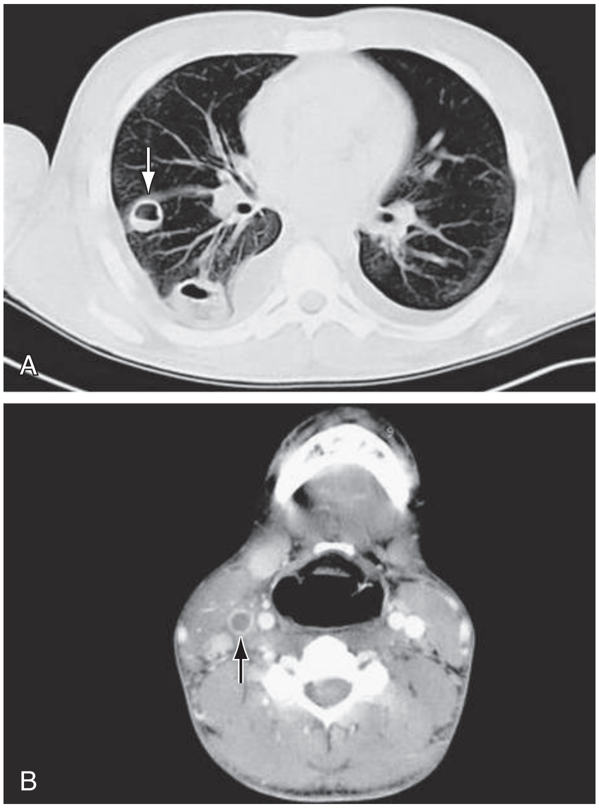

Figure 382-3 CT of Lemierre disease. **A,** CT demonstrating nodular appearance of pulmonary infiltrates *(arrow)*. **B,** CT of neck demonstrating thrombosis of right internal jugular vein *(arrow)*. *(From Plymyer MR, Zoccola DC, Tallarita G: An 18 year old man presenting with sepsis following a recent pharyngeal infection*, Arch Pathol Lab Med *128:813, 2004. history of recurrent peritonsillar abscess or recurrent tonsillitis, or complications from peritonsillar abscess. The feared, albeit rare, complication is rupture of the abscess, with resultant aspiration pneumonitis. There is a 10% recurrence risk for peritonsillar abscess.

Chapter 383
Tonsils and Adenoids

Ralph F. Wetmore

ANATOMY

The *Waldeyer ring* (the lymphoid tissue surrounding the opening of the oral and nasal cavities into the pharynx) comprises the palatine tonsils, the pharyngeal tonsil or adenoid, lymphoid tissue surrounding the eustachian tube orifice in the lateral walls of the nasopharynx, the lingual tonsil at the base of the tongue, and scattered lymphoid tissue throughout the remainder of the pharynx, particularly behind the posterior pharyngeal pillars and along the posterior pharyngeal wall. The *palatine tonsil* consists of lymphoid tissue located between the palatoglossal fold (anterior tonsillar pillar) and the palatopharyngeal fold (posterior tonsillar pillar) forms. This lymphoid tissue is separated from the surrounding pharyngeal musculature by a thick fibrous capsule. The *adenoid* is a single aggregation of lymphoid tissue that occupies the space between the nasal septum and the posterior pharyngeal wall. A thin fibrous capsule separates it from the underlying structures; the adenoid does not contain the complex crypts that are found in the palatine tonsils but rather more simple crypts. Lymphoid tissue at the base of the tongue forms the *lingual tonsil* that also contains simple tonsillar crypts.

NORMAL FUNCTION

Located at the opening of the pharynx to the external environment, the tonsils and adenoid are well situated to provide primary defense against foreign matter. The immunologic role of the tonsils and adenoids is to induce secretory immunity and to regulate the production of the secretory immunoglobulins. Deep crevices within tonsillar tissue form tonsillar crypts that are lined with squamous epithelium and host a concentration of lymphocytes at their bases. The lymphoid tissue of the Waldeyer ring is most immunologically active between 4 and 10 yr of age, with a decrease after puberty. Adenotonsillar hypertrophy is greatest between ages 3 and 6 yr; in most children tonsils begin to involute after age 8 yr. No major immunologic deficiency has been demonstrated after removal of either or both of the tonsils and adenoid.

PATHOLOGY

Acute Infection

Most episodes of acute pharyngotonsillitis are caused by viruses (see Chapter 381). Group A β-hemolytic streptococcus (GABHS) is the most common cause of bacterial infection in the pharynx (see Chapter 183).

Chronic Infection

The tonsils and adenoids can be chronically infected by multiple microbes, which can include a high incidence of β-lactamase–producing organisms. Both aerobic species, such as streptococci and *Haemophilus influenzae,* and anaerobic species, such as *Peptostreptococcus, Prevotella,* and *Fusobacterium,* contribute. The tonsillar crypts can accumulate desquamated epithelial cells, lymphocytes, bacteria, and other debris, causing cryptic tonsillitis. With time, these cryptic plugs can calcify into tonsillar concretions or tonsillolith. Biofilms appear to play a role in chronic inflammation of the tonsils.

Airway Obstruction

Both the tonsils and adenoids are a major cause of upper airway obstruction in children. Airway obstruction in children is typically manifested in sleep-disordered breathing, including obstructive sleep apnea, obstructive sleep hypopnea, and upper airway resistance syndrome (see Chapter 19). Sleep-disordered breathing secondary to adenotonsillar breathing is a cause of growth failure (see Chapter 41).

Tonsillar Neoplasm

Rapid enlargement of one tonsil is highly suggestive of a tonsillar malignancy, typically lymphoma in children.

CLINICAL MANIFESTATIONS

Acute Infection

Symptoms of GABHS infection include odynophagia, dry throat, malaise, fever and chills, dysphagia, referred otalgia, headache, muscular aches, and enlarged cervical nodes. Signs include dry tongue, erythematous enlarged tonsils, tonsillar or pharyngeal exudate, palatine petechiae, and enlargement and tenderness of the jugulodigastric lymph nodes (Fig. 383-1; see Chapters 183 and 381).

Chronic Infection

Children with chronic or cryptic tonsillitis often present with halitosis, chronic sore throats, foreign-body sensation, or a history of expelling foul-tasting and foul-smelling cheesy lumps. Examination reveals

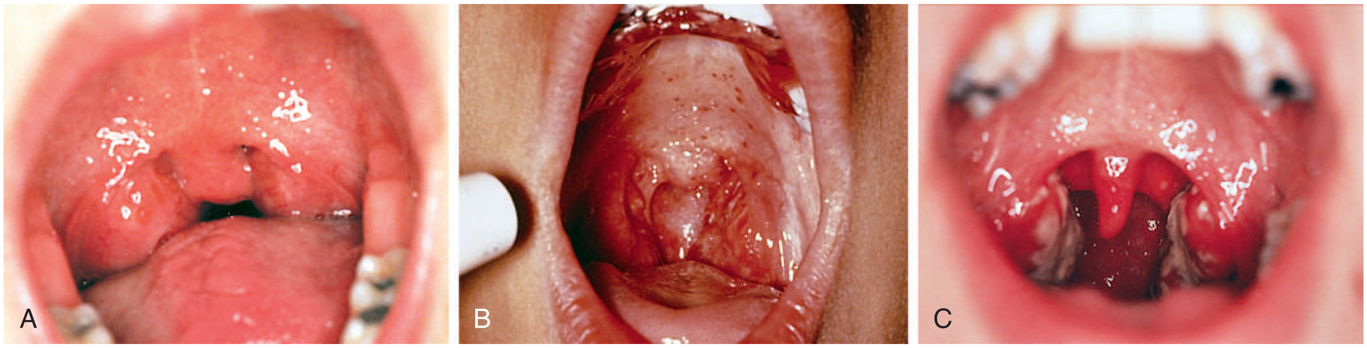

Figure 383-1 Pharyngotonsillitis. This common syndrome has a number of causative pathogens and a wide spectrum of severity. **A,** The diffuse tonsillar and pharyngeal erythema seen here is a nonspecific finding that can be produced by a variety of pathogens. **B,** This intense erythema, seen in association with acute tonsillar enlargement and palatal petechiae, is highly suggestive of group A β-streptococcal infection, though other pathogens can produce these findings. **C,** This picture of exudative tonsillitis is most commonly seen with either group A streptococcal or Epstein-Barr virus infection. *(B courtesy of Michael Sherlock, MD, Lutherville, MD. From Yellon RF, McBride TP, Davis HW: Otolaryngology. In Zitelli BJ, Davis HW, editors:* Atlas of pediatric physical diagnosis, *ed 4, Philadelphia, 2002, Mosby, p. 852.)*

tonsils of a range of sizes which often they contain copious debris within the crypts. The offending organism is not usually GABHS.

Airway Obstruction

The diagnosis of airway obstruction (see Chapter 19) can frequently be made by history and physical examination. Daytime symptoms of airway obstruction, secondary to adenotonsillar hypertrophy, include chronic mouth breathing, nasal obstruction, hyponasal speech, hyposmia, decreased appetite, poor school performance, and, rarely, symptoms of right-sided heart failure. Nighttime symptoms consist of loud snoring, choking, gasping, frank apnea, restless sleep, abnormal sleep positions, somnambulism, night terrors, diaphoresis, enuresis, and sleep talking. Large tonsils are typically seen on examination, although the absolute size might not indicate the degree of obstruction. The size of the adenoid tissue can be demonstrated on a lateral neck radiograph or with flexible endoscopy. Other signs that can contribute to airway obstruction include the presence of a craniofacial syndrome or hypotonia.

Tonsillar Neoplasm

The rapid unilateral enlargement of a tonsil, especially if accompanied by systemic signs of night sweats, fever, weight loss, and lymphadenopathy, is highly suggestive of a tonsillar malignancy. The diagnosis of a tonsillar malignancy should also be entertained if the tonsil appears grossly abnormal. Among 54,901 patients undergoing tonsillectomy, 54 malignancies were identified (0.087% prevalence); all but 6 malignancies had been suspected based on suspicious anatomic features preoperatively.

TREATMENT

Medical Management

The treatment of acute pharyngotonsillitis is discussed in Chapter 381 and antibiotic treatment of GABHS in Chapter 183. Because copathogens such as staphylococci or anaerobes can produce β-lactamase that can inactivate penicillin, the use of cephalosporins or clindamycin may be more efficacious in the treatment of chronic throat infections. Tonsillolith or debris may be expressed manually with either a cotton-tipped applicator or a water jet. Chronically infected tonsillar crypts can be cauterized using silver nitrate.

Tonsillectomy

Tonsillectomy alone is most commonly performed for recurrent or chronic pharyngotonsillitis. Tonsillectomy has been shown to be effective in reducing the number of infections and the symptoms of chronic tonsillitis such as halitosis, persistent or recurrent sore throats, and recurrent cervical adenitis. In resistant cases of cryptic tonsillitis, tonsillectomy may be curative. Rarely in children, tonsillectomy is indicated for biopsy of a unilaterally enlarged tonsil to exclude a neoplasm or to treat recurrent hemorrhage from superficial tonsillar blood vessels. Tonsillectomy has not been shown to offer clinical benefit over conservative treatment in children with mild symptoms.

Table 383-1 Paradise Criteria for Tonsillectomy

CRITERION	DEFINITION
Minimum frequency of sore throat episodes	At least 7 episodes in the previous year, at least 5 episodes in each of the previous 2 yr, or at least 3 episodes in each of the previous 3 yr
Clinical features	Sore throat plus at least 1 of the following features qualifies as a counting episode: Temperature of greater than 38.3°C (100.9°F) Cervical adenopathy (tender lymph nodes or lymph node size >2 cm) Tonsillar exudate Culture positive for group A β-hemolytic streptococcus
Treatment	Antibiotics administered in the conventional dosage for proved or suspected streptococcal episodes
Documentation	Each episode of throat infection and its qualifying features substantiated by contemporaneous notation in a medical record If the episodes are not fully documented, subsequent observance by the physician of 2 episodes of throat infection with patterns of frequency and clinical features consistent with the initial history*

*Allows for tonsillectomy in patients who meet all but the documentation criterion. A 12 mo observation period is usually recommended before consideration of tonsillectomy.

Adapted from Baugh RF, Archer SM, Mitchell RB, et al: American Academy of Otolaryngology–Head and Neck Surgery Foundation. Clinical practice guideline: tonsillectomy in children. Otolaryngol Head Neck Surg *144(1 Suppl):S8, 2011, Table 5.*

There are large variations in surgical rates among children across countries: 144 in 10,000 in Italy; 115 in 10,000 in the Netherlands; 65 in 10,000 in England; and 50 in 10,000 in the United States. Rates are generally higher in boys. With the issuance of practice guidelines, these variations may decrease. The American Academy of Otolaryngology (AAO)–Head and Neck Surgery *Taskforce on Clinical Practice Guidelines: Tonsillectomy in Children* issued evidence-based guidelines in 2011 (Table 383-1). Table 383-2 illustrates the differences and

Table 383-2 Comparison of American, Italian, and Scottish Guidelines for Tonsillectomy in Children and Adolescents

PARAMETER	AAO-HNS GUIDELINES	ITALIAN GUIDELINES	SCOTTISH GUIDELINES
Audience	Multidisciplinary	Multidisciplinary	Multidisciplinary
Target population	Children and adolescents 1-18 yr of age	Children and adults	Children 4-16 yr of age and adults
Scope	Treatment of children who are candidates for tonsillectomy	Appropriateness and safety of tonsillectomy	Management of sore throat and indications for tonsillectomy
Methods	Based on a priori protocol, systematic literature review, American Academy of Pediatrics scale of evidence quality	Systematic literature review, Italian National Program Guidelines scale of evidence quality	Based on a priori protocol, systematic literature review, Scottish Intercollegiate Guidelines Network scale of evidence quality
Recommendations			
Recurrent infection	Tonsillectomy is an option for children with recurrent throat infection that meets the Paradise criteria (see Table 383-1) for frequency, severity, treatment, and documentation of illness	Tonsillectomy is indicated in patients with at least 1 yr of recurrent tonsillitis (5 or more episodes per year) that is disabling and impairs normal activities, but only after an additional 6 mo of watchful waiting to assess the pattern of symptoms using a clinical diary	Tonsillectomy should be considered for recurrent, disabling sore throat caused by acute tonsillitis when the episodes are well documented, are adequately treated, and meet the Paradise criteria (see Table 383-1) for frequency of illness
Pain control	Recommendation to advocate for pain relief (e.g., provide information, prescribe) and educate caregivers about the importance of managing and reassessing pain	Recommendation for acetaminophen before and after surgery	Recommendation for adequate dose of acetaminophen for pain relief in children
Antibiotic use	Recommendation against perioperative antibiotics	Recommendation for short-term perioperative antibiotics*	NA
Steroid use	Recommendation for a single intraoperative dose of dexamethasone	Recommendation for a single intraoperative dose of dexamethasone	Recommendation for a single intraoperative dose of dexamethasone
Sleep-disordered breathing	Recommendation to counsel caregivers about tonsillectomy as a means to improve health in children with sleep-disordered breathing and comorbid conditions	Recommendation for diagnostic testing in children with suspected sleep respiratory disorders	NA
Polysomnography	Recommendation to counsel caregivers about tonsillectomy as a means to improve health in children with abnormal polysomnography	Recommendation for polysomnography when pulse oximetry results are not conclusive in agreement with Brouillette criteria	NA
Surgical technique	NA	Recommendation for "cold" technique	NA
Hemorrhage	Recommendation that the surgeon document primary and secondary hemorrhage after tonsillectomy at least annually	NA	NA
Adjunctive therapy	NA	NA	Recommendation against *Echinacea purpurea* for treatment of sore throat Recommendation for acupuncture in patients at risk of postoperative nausea and vomiting who cannot take antiemetic drugs

*Statement made prior to most recent Cochrane review.

similarities between these guidelines with those of the other major professional groups across the globe.

Adenoidectomy

Adenoidectomy alone may be indicated for the treatment of chronic nasal infection (chronic adenoiditis), chronic sinus infections that have failed medical management, and recurrent bouts of acute otitis media, including those in children with tympanostomy tubes who suffer from recurrent otorrhea. Adenoidectomy may be helpful in children with chronic or recurrent otitis media with effusion. Adenoidectomy alone may be curative in the management of patients with nasal obstruction, chronic mouth breathing, and loud snoring suggesting sleep-disordered breathing. Adenoidectomy may also be indicated for children in whom upper airway obstruction is suspected of causing craniofacial or occlusive developmental abnormalities.

Tonsillectomy and Adenoidectomy

The criteria for both tonsillectomy and adenoidectomy for recurrent infection are the same as those for tonsillectomy alone. The other major indication for performing both procedures together is upper airway obstruction secondary to adenotonsillar hypertrophy that results in sleep-disordered breathing, failure to thrive, craniofacial or occlusive developmental abnormalities, speech abnormalities, or, rarely, cor pulmonale. A high proportion of children with failure to thrive in the context of adenotonsillar hypertrophy resulting in sleep disorder experiences significant growth acceleration after adenotonsillectomy.

COMPLICATIONS

Poststreptococcal Glomerulonephritis and Acute Rheumatic Fever

The 2 major complications of untreated GABHS infection are poststreptococcal glomerulonephritis and acute rheumatic fever (see Chapters 511.1 and 183).

Peritonsillar Infection

Peritonsillar infection can occur as either cellulitis or a frank abscess in the region superior and lateral to the tonsillar capsule (see Chapter 381). These infections usually occur in children with a history of recurrent tonsillar infection and are polymicrobial, including both aerobes and anaerobes. Unilateral throat pain, referred otalgia, drooling, and trismus are presenting symptoms. The affected tonsil is displaced down and medial by swelling of the anterior tonsillar pillar and palate. The diagnosis of an abscess can be confirmed by CT or by needle aspiration, the contents of which should be sent for culture.

Retropharyngeal Space Infection

Infections in the retropharyngeal space develop in the lymph nodes that drain the oropharynx, nose, and nasopharynx (see Chapter 382).

Parapharyngeal Space Infection

Tonsillar infection can extend into the parapharyngeal space, causing symptoms of fever, neck pain and stiffness, and signs of swelling of the lateral pharyngeal wall and neck on the affected side. The diagnosis is confirmed by contrast medium–enhanced CT, and treatment includes intravenous antibiotics and external incision and drainage if an abscess is demonstrated on CT (see Chapter 382). Septic thrombophlebitis of the jugular vein, **Lemierre syndrome,** manifests with fever, toxicity, neck pain and stiffness, and respiratory distress as a result of multiple septic pulmonary emboli and is a complication of a parapharyngeal space or odontogenic infection from *Fusobacterium necrophorum*. Concurrent Epstein-Barr virus mononucleosis (see Chapter 254) can be a predisposing event before the sudden onset of fever, chills, and respiratory distress in an adolescent patient. Treatment includes high-dose intravenous antibiotics (ampicillin-sulbactam, clindamycin, penicillin, or ciprofloxacin) and heparinization.

Recurrent or Chronic Pharyngotonsillitis

See Chapter 381.

CHRONIC AIRWAY OBSTRUCTION

Although rare, children with chronic airway obstruction from enlarged tonsils and adenoids can present with cor pulmonale.

The effects of chronic airway obstruction and mouth breathing on facial growth remain a subject of controversy. Studies of chronic mouth breathing, both in humans and animals, have shown changes in facial development, including prolongation of the total anterior facial height and a tendency toward a retrognathic mandible, the so-called adenoid facies. Adenotonsillectomy can reverse some of these abnormalities. Other studies have disputed these findings.

Tonsillectomy and Adenoidectomy

The risks and potential benefits of surgery must be considered (Table 383-3). Bleeding can occur in the immediate postoperative period or be delayed (consider von Willebrand disease) after separation of the eschar. The Clinical Guidelines for Tonsillectomy include a recommendation for a single intravenous dose of intraoperative dexamethasone (0.5 mg/kg), which decreases postoperative nausea and vomiting and reduces swelling. There is no evidence that use of dexamethasone in postoperative tonsillectomy patients results in an increased risk of postoperative bleeding. Routine use of antibiotics in the postoperative period is ineffective and thus the American Academy of Otolaryngology Clinical Practice Guidelines advise against its use, although this recommendation is not consistent among the major professional organizations who have issued guidelines (see Table 383-2). Codeine is associated with excessive sedation and fatalities and is not recommended.

Swelling of the tongue and soft palate can lead to acute airway obstruction in the 1st few hr after surgery. Children with underlying hypotonia or craniofacial anomalies are at greater risk for suffering this complication. Dehydration from odynophagia is not uncommon in the 1st postoperative week. Rare complications include velopharyngeal insufficiency, nasopharyngeal or oropharyngeal stenosis, and psychologic problems.

Table 383-3 Risks and Potential Benefits of Tonsillectomy or Adenoidectomy or Both

RISKS
Cost*
Risk of anesthetic accidents
Malignant hyperthermia
Cardiac arrhythmia
Vocal cord trauma
Aspiration with resulting bronchopulmonary obstruction or infection
Risk of miscellaneous surgical or postoperative complications
Hemorrhage
Airway obstruction from edema of tongue, palate, or nasopharynx, or retropharyngeal hematoma
Central apnea
Prolonged muscular paralysis
Dehydration
Palatopharyngeal insufficiency
Otitis media
Nasopharyngeal stenosis
Refractory torticollis
Facial edema
Emotional upset
Unknown risks
POTENTIAL BENEFITS
Reduction in frequency of ear, nose, throat illness, and thus in
Discomfort
Inconvenience
School absence
Parental anxiety
Work missed by parents
Costs of physician visits and drugs
Reduction in nasal obstruction with improved
Respiratory function
Comfort
Sleep
Craniofacial growth and development
Appearance
Reduction in hearing impairment
Improved growth and overall well-being
Reduction in long-term parental anxiety

*Cost for tonsillectomy alone and adenoidectomy alone are somewhat lower.

Chapter 384

Chronic or Recurrent Respiratory Symptoms

Anne G. Griffiths and Thomas P. Green

Respiratory tract symptoms, including cough, wheeze, and stridor, occur frequently or persist for long periods in a substantial number of children; other children have persistent or recurring lung infiltrates with or without symptoms. Determining the cause of these chronic findings can be difficult because symptoms can be caused by a close succession of unrelated acute respiratory tract infections or by a single pathophysiologic process. Specific and easily performed diagnostic tests do not exist for many acute and chronic respiratory conditions. Pressure from the affected child's family for a quick remedy because of concern over symptoms related to breathing may complicate diagnostic and therapeutic efforts.

A systematic approach to the diagnosis and treatment of these children consists of assessing whether the symptoms are the manifestation of a minor problem or a life-threatening process; determining the most likely underlying pathogenic mechanism; selecting the simplest effective therapy for the underlying process, which often is only symptomatic therapy; and carefully evaluating the effect of therapy. Failure of this approach to identify the process responsible or to effect improvement signals the need for more extensive and perhaps invasive diagnostic efforts, including bronchoscopy.

JUDGING THE SERIOUSNESS OF CHRONIC RESPIRATORY COMPLAINTS

Clinical manifestations suggesting that a respiratory tract illness may be life-threatening or associated with the potential for chronic disability are listed in Table 384-1. If none of these findings is detected, the chronic respiratory process is more likely to be benign. Active, well-nourished, and appropriately growing infants who present with intermittent noisy breathing but no other physical or laboratory abnormalities require only symptomatic treatment and parental reassurance. Benign-appearing but persistent symptoms are occasionally the harbinger of a serious lower respiratory tract problem. By contrast, occasionally children (e.g., infection-related asthma) have recurrent life-threatening episodes but few or no symptoms in the intervals. Repeated examinations over an extended period, both when the child appears healthy and when the child is symptomatic, may be helpful in sorting out the severity and chronicity of lung disease.

Table 384-1	Indicators of Serious Chronic Lower Respiratory Tract Disease in Children
Persistent fever	
Ongoing limitation of activity	
Failure to grow	
Failure to gain weight appropriately	
Clubbing of the digits	
Persistent tachypnea and labored ventilation	
Shortness of breath and exercise intolerance	
Chronic purulent sputum	
Persistent hyperinflation	
Substantial and sustained hypoxemia	
Refractory infiltrates on chest x-ray	
Persistent pulmonary function abnormalities	
Family history of heritable lung disease	
Cyanosis and hypercarbia	

RECURRENT OR PERSISTENT COUGH

Cough is a reflex response of the lower respiratory tract to stimulation of irritant or cough receptors in the airways' mucosa. The most common cause in children is airway reactivity (asthma). Because cough receptors also reside in the pharynx, paranasal sinuses, stomach, and external auditory canal, the source of a persistent cough may need to be sought beyond the lungs. Specific lower respiratory stimuli include excessive secretions, aspirated foreign material, inhaled dust particles or noxious gases, cold or dry air, and an inflammatory response to infectious agents or allergic processes. Table 384-2 lists some of the conditions responsible for chronic cough.

Table 384-3 presents characteristics of cough that can aid in distinguishing a cough's origin. Additional useful information can include a history of atopic conditions (asthma, eczema, urticaria, allergic rhinitis), a seasonal or environmental variation in frequency or intensity of cough, and a strong family history of atopic conditions, all suggesting an allergic cause; symptoms of malabsorption or family history indicating cystic fibrosis; symptoms related to feeding, suggesting aspiration or gastroesophageal reflux; a choking episode, suggesting foreign-body aspiration; headache or facial edema associated with sinusitis; and a smoking history in older children and adolescents or the presence of a smoker in the house (Table 384-4).

The physical examination can provide much information pertaining to the cause of chronic cough. Posterior pharyngeal drainage combined with a nighttime cough suggests chronic upper airway disease such as sinusitis. An overinflated chest suggests chronic airway obstruction, as

Table 384-2	Differential Diagnosis of Recurrent and Persistent Cough in Children
RECURRENT COUGH	
Reactive airway disease (asthma)	
Drainage from upper airways	
Aspiration	
Frequently recurring respiratory tract infections in immunocompetent or immunodeficient patients	
Symptomatic Chiari malformation	
Idiopathic pulmonary hemosiderosis	
Hypersensitivity (allergic) pneumonitis	
PERSISTENT COUGH	
Hypersensitivity of cough receptors after infection	
Reactive airway disease (asthma)	
Chronic sinusitis	
Chronic rhinitis (allergic or nonallergic)	
Bronchitis or tracheitis caused by infection or smoke exposure	
Bronchiectasis, including cystic fibrosis, primary ciliary dyskinesia, immunodeficiency	
Habit cough	
Foreign-body aspiration	
Recurrent aspiration owing to pharyngeal incompetence, tracheolaryngoesophageal cleft, or tracheoesophageal fistula	
Gastroesophageal reflux, with or without aspiration	
Pertussis	
Extrinsic compression of the tracheobronchial tract (vascular ring, neoplasm, lymph node, lung cyst)	
Tracheomalacia, bronchomalacia	
Endobronchial or endotracheal tumors	
Endobronchial tuberculosis	
Hypersensitivity pneumonitis	
Fungal infections	
Inhaled irritants, including tobacco smoke	
Irritation of external auditory canal	
Angiotensin-converting enzyme inhibitors	

Table 384-3 Characteristics of Cough and Other Clinical Features and Possible Causes

SYMPTOMS AND SIGNS	POSSIBLE UNDERLYING ETIOLOGY*
Auscultatory findings (wheeze, crepitations/crackles, differential breath sounds)	Asthma, bronchitis, congenital lung disease, foreign body aspiration, airway abnormality
Cough characteristics (e.g., cough with choking, cough quality, cough starting from birth)	See text; congenital lung abnormalities
Cardiac abnormalities (including murmurs)	Any cardiac illness
Chest pain	Asthma, functional, pleuritis
Chest wall deformity	Any chronic lung disease
Daily moist or productive cough	Chronic bronchitis, suppurative lung disease
Digital clubbing	Suppurative lung disease, arteriovenous shunt
Dyspnea (exertional or at rest)	Compromised lung function of any chronic lung or cardiac disease
Failure to thrive	Compromised lung function, immunodeficiency, cystic fibrosis
Feeding difficulties (including choking and vomiting)	Compromised lung function, aspiration
Hemoptysis	Bronchitis, foreign body aspiration, suctioning trauma
Immune deficiency	Atypical and typical recurrent respiratory infections
Medications or drugs	Angiotensin-converting enzyme inhibitors, puffers, illicit drug use
Neurodevelopmental abnormality	Aspiration
Recurrent pneumonia	Immunodeficiency, congenital lung problem, airway abnormality
Symptoms of upper respiratory tract infection	Can coexist or be a trigger for an underlying problem

*This is not an exhaustive list; only the more common respiratory diseases are mentioned.

Table 384-4 Clinical Clues About Cough

CHARACTERISTIC	THINK OF
Staccato, paroxysmal	Pertussis, cystic fibrosis, foreign body, *Chlamydia* spp., *Mycoplasma* spp.
Followed by "whoop"	Pertussis
All day, never during sleep	Habit cough
Barking, brassy	Croup, habit cough, tracheomalacia, tracheitis, epiglottitis
Hoarseness	Laryngeal involvement (croup, recurrent laryngeal nerve involvement)
Abrupt onset	Foreign body, pulmonary embolism
Follows exercise	Reactive airway disease
Accompanies eating, drinking	Aspiration, gastroesophageal reflux, tracheoesophageal fistula
Throat clearing	Postnasal drip, vocal tic
Productive (sputum)	Infection, cystic fibrosis, bronchiectasis
Night cough	Sinusitis, reactive airway disease, gastroesophageal reflux
Seasonal	Allergic rhinitis, reactive airway disease
Immunosuppressed patient	Bacterial pneumonia, *Pneumocystis jiroveci, Mycobacterium tuberculosis, Mycobacterium avium-intracellulare,* cytomegalovirus
Dyspnea	Hypoxia, hypercarbia
Animal exposure	*Chlamydia psittaci* (birds), *Yersinia pestis* (rodents), *Francisella tularensis* (rabbits), Q fever (sheep, cattle), hantavirus (rodents), histoplasmosis (pigeons)
Geographic	Histoplasmosis (Mississippi, Missouri, Ohio River Valley), coccidioidomycosis (Southwest), blastomycosis (North and Midwest)
Workdays with clearing on days off	Occupational exposure

From Kliegman RM, Greenbaum LA, Lyle PS: Practical strategies in pediatric diagnosis and therapy, *ed 2, Philadelphia, 2004, WB Saunders, p. 19.*

in asthma or cystic fibrosis. An expiratory wheeze, with or without diminished intensity of breath sounds, strongly suggests asthma or asthmatic bronchitis but may also be consistent with a diagnosis of cystic fibrosis, bronchomalacia, vascular ring, aspiration of foreign material, or pulmonary hemosiderosis. Careful auscultation during forced expiration may reveal expiratory wheezes that are otherwise undetectable and that are the only indication of underlying reactive airways. Coarse crackles suggest bronchiectasis, including cystic fibrosis, but can also occur with an acute or subacute exacerbation of asthma. Clubbing of the digits is seen in most patients with bronchiectasis but in only a few other respiratory conditions with chronic cough (see Table 384-2). Tracheal deviation suggests foreign body aspiration or a mediastinal mass.

Allowing sufficient examination time to detect a spontaneous cough is important. If a spontaneous cough does not occur, asking the child to take a maximal breath and forcefully exhale repeatedly usually induces a cough reflex. Most children can cough on request by 4-5 yr of age. Children who cough as often as several times a minute with regularity are likely to have a habit (tic) cough (see Chapter 24). If the cough is loose, every effort should be made to obtain sputum; many older children can comply. It is sometimes possible to pick up small bits of sputum with a throat swab quickly inserted into the lower pharynx while the child coughs with the tongue protruding. Clear mucoid sputum is most often associated with an allergic reaction or asthmatic bronchitis. Cloudy (purulent) sputum suggests a respiratory tract infection but can also reflect increased cellularity (eosinophilia) from an asthmatic process. Very purulent sputum is characteristic of bronchiectasis (see Chapter 401). Malodorous expectorations suggest anaerobic infection of the lungs. In cystic fibrosis (see Chapter 403), the sputum, even when purulent, is rarely foul smelling.

Laboratory tests can help in the evaluation of a chronic cough. Only sputum specimens containing alveolar macrophages should be interpreted as reflecting lower respiratory tract processes. Sputum eosinophilia suggests asthma, asthmatic bronchitis, or hypersensitivity reactions of the lung (see Chapter 391), but a polymorphonuclear cell response suggests infection; if sputum is unavailable, the presence of eosinophilia in nasal secretions also suggests atopic disease. If most of the cells in sputum are macrophages, postinfectious hypersensitivity of cough receptors should be suspected. Sputum macrophages can be stained for hemosiderin content, which is diagnostic of pulmonary hemosiderosis (see Chapter 400), or for lipid content, which in large amounts suggests, but is not specific for, repeated aspiration. Rarely, children may expectorate partial casts of the airway which can be characterized in investigating causes of plastic bronchitis. Children whose coughs persist for more than 6 wk should be tested for cystic fibrosis regardless of their race or ethnicity (see Chapter 403). Sputum culture is helpful in evaluation of cystic fibrosis, but less so for other conditions because throat flora can contaminate the sample.

Hematologic assessment can reveal a microcytic anemia that is the result of pulmonary hemosiderosis (see Chapter 406) or hemoptysis, or eosinophilia that accompanies asthma and other hypersensitivity reactions of the lung. Infiltrates on the chest radiograph suggest cystic fibrosis, bronchiectasis, foreign body, hypersensitivity pneumonitis, or tuberculosis. When asthma-equivalent cough is suggested, a trial of bronchodilator therapy may be diagnostic. If the cough does not respond to initial therapeutic efforts, more-specific diagnostic procedures may be warranted, including an immunologic or allergic evaluation, chest and paranasal sinus imaging, esophagograms, tests for gastroesophageal reflux (see Chapter 323), and special microbiologic studies including rapid viral testing. Evaluation of ciliary morphology, nasal endoscopy, laryngoscopy and bronchoscopy may also be indicated.

Habit cough ("psychogenic cough" or "cough tic") must be considered in any child with a cough that has lasted for weeks or months, that has been refractory to treatment, and that disappears with sleep or with distraction. Typically, the cough is abrupt and loud and has a harsh, honking, or "barking" quality. A disassociation between the intensity of the cough and the child's affect is typically striking. This cough may be absent if the physician listens outside the examination room, but it will reliably appear immediately on direct attention to the child and the symptom. It typically begins with an upper respiratory infection but then lingers. The child misses many days of school because the cough disrupts the classroom. This disorder accounts for many unnecessary medical procedures and courses of medication. It is treatable with assurance that a pathologic lung condition is absent and that the child should resume full activity, including school. This assurance, together with speech therapy techniques that allow the child to reduce musculoskeletal tension in the neck and chest and that increase the child's awareness of the initial sensations that trigger cough, has been very successful. Self-hypnosis is another successful therapy, often effective with 1 session. The designation "habit cough" is preferable to "psychogenic cough" because it carries no stigma and because most of these children do not have significant emotional problems. When the cough disappears, it does not reemerge as another symptom. Nonetheless, other symptoms such as irritable bowel syndrome may be present in the patient or family.

FREQUENTLY RECURRING OR PERSISTENT STRIDOR

Stridor, a harsh, medium-pitched, inspiratory sound associated with obstruction of the laryngeal area or the extrathoracic trachea, is often accompanied by a croupy cough and hoarse voice. Stridor is most commonly observed in children with croup (see Chapter 385); foreign bodies and trauma can also cause acute stridor. A few children, however, acquire recurrent stridor or have persistent stridor from the 1st days or weeks of life (Table 384-5). Most congenital anomalies of large airways that produce stridor become symptomatic soon after birth. Increase of stridor when a child is supine suggests laryngomalacia or tracheomalacia. It is important to note that when evaluating for a specific anatomic cause of abnormal breath sounds, it is not uncommon to identify additional congenital anomalies of the airway. An accompanying history of hoarseness or aphonia suggests involvement of the vocal cords. Associated dysphagia may also suggest a vascular ring. In a child with intermittent stridor that accompanies physical activity and is not responsive to asthma therapies, paradoxical vocal cord dysfunction may be of consideration. Paradoxical vocal cord dysfunction may be highly supported by history and confirmed by laryngoscopy during an exercise challenge test if symptoms are successfully elicited. Speech therapy and behavior modification may be therapeutic.

Gastroesophageal reflux
Macroglossia, Pierre Robin syndrome
Cri-du-chat syndrome
Paradoxical vocal cord dysfunction
Hypocalcemia
Vocal cord paralysis
Chiari crisis
Severe neonatal episodic laryngospasm caused by *SCN4A* mutation

Physical examination for recurrent or persistent stridor is usually unrewarding, although changes in its severity and intensity due to changes of body position should be assessed. Anteroposterior and lateral radiographs, contrast esophagography, fluoroscopy, CT, and MRI are potentially useful diagnostic tools. In most cases, direct observation by laryngoscopy is necessary for definitive diagnosis. Undistorted views of the larynx are best obtained with fiberoptic laryngoscopy.

RECURRENT OR PERSISTENT WHEEZE

See also Chapter 391.

Parents often complain that their child "wheezes," when, in fact, they are reporting respiratory sounds that are audible without a stethoscope, produce palpable resonance throughout the chest, and occur most

prominently in inspiration. Some of these children have stridor, although many have audible sounds when the supraglottic airway is incompletely cleared of feedings or secretions.

True **wheezing** is a relatively common and particularly troublesome manifestation of obstructive *lower* respiratory tract disease in children. The site of obstruction may be anywhere from the intrathoracic trachea to the small bronchi or large bronchioles, but the sound is generated by turbulence in larger airways that collapse with forced expiration (see Chapter 373). Children younger than 2-3 yr are especially prone to wheezing, because bronchospasm, mucosal edema, and accumulation of excessive secretions have a relatively greater obstructive effect on their smaller airways. In addition, the compliant airways in young children collapse more readily with active expiration. Isolated episodes of acute wheezing, such as can occur with bronchiolitis, are not uncommon, but wheezing that recurs or persists for more than 4 wk suggests other diagnoses (see Table 391-1 in Chapter 391). Most recurrent or persistent wheezing in children is the result of airway reactivity. Nonspecific environmental factors such as cigarette smoke may be important contributors.

Frequently recurring or persistent wheezing starting at or soon after birth suggests a variety of other diagnoses, including congenital structural abnormalities involving the lower respiratory tract or tracheobronchomalacia (see Chapter 386.11). Wheezing that attends cystic fibrosis is most common in the 1st yr of life. Sudden onset of severe wheezing in a previously healthy child should suggest foreign-body aspiration.

Either wheezing or coughing when associated with tachypnea and hypoxemia may be suggestive of **interstitial lung disease** (see Chapter 399.5). However, many patients with interstitial lung disease demonstrate no symptoms other than rapid breathing on initial physical examination. Although chest roentgenograms may be normal in interstitial lung disease, diffuse abnormalities on chest X-ray may support further evaluation in patients suspected to have interstitial lung disease with characteristic findings described on high-resolution CT scan and lung biopsy.

Repeated examination may be required to verify a history of wheezing in a child with episodic symptoms and should be directed toward assessing air movement, ventilatory adequacy, and evidence of chronic lung disease, such as fixed overinflation of the chest, growth failure, and digital clubbing. Patients should be assessed for oropharyngeal dysphagia in cases of suspected recurrent aspiration. Clubbing suggests chronic lung infection and is rarely prominent in uncomplicated asthma. Tracheal deviation from foreign body aspiration should be sought. It is essential to rule out wheezing secondary to congestive heart failure. Allergic rhinitis, urticaria, eczema, or evidence of ichthyosis vulgaris suggests asthma or asthmatic bronchitis. The nose should be examined for polyps, which can exist with allergic conditions or cystic fibrosis.

Sputum eosinophilia and elevated serum immunoglobulin E levels suggest allergic reactions. A forced expiratory volume in 1 sec increase of 15% in response to bronchodilators confirms reactive airways. Specific microbiologic studies, special imaging studies of the airways and cardiovascular structures, diagnostic studies for cystic fibrosis, and bronchoscopy (see Chapter 366) should be considered if the response is unsatisfactory.

RECURRENT AND PERSISTENT LUNG INFILTRATES

Radiographic lung infiltrates resulting from acute pneumonia usually resolve within 1-3 wk, but a substantial number of children, particularly infants, fail to completely clear infiltrates within a 4 wk period. These children may be febrile or afebrile and may display a wide range of respiratory symptoms and signs. Persistent or recurring infiltrates present a diagnostic challenge (Table 384-6).

Symptoms associated with chronic lung infiltrates in the 1st several weeks of life (but not related to neonatal respiratory distress syndrome) suggest infection acquired in utero or during descent through the birth canal. Early appearance of chronic infiltrates can also be associated with cystic fibrosis or congenital anomalies that result in aspiration or

Sarcoidosis

airway obstruction. A history of recurrent infiltrates, wheezing, and cough may reflect asthma, even in the 1st yr of life.

A controversial association has been posed regarding recurrent lung infiltrates in pulmonary hemosiderosis related to cow's milk hypersensitivity or unknown causes appearing in the 1st yr of life. Children with a history of bronchopulmonary dysplasia often have episodes of respiratory distress attended by wheezing and new lung infiltrates. Recurrent pneumonia in a child with frequent otitis media, nasopharyngitis, adenitis, or dermatologic manifestations suggests an immunodeficiency state, complement deficiency, or phagocytic defect (see Chapters 124-127). Primary ciliary dyskinesia is also of consideration in patients with frequent otitis media and suppurative sinopulmonary disease, with or without accompanying heterotaxy or infertility. Pulmonary sequestration may be suspected in patients with recurrent findings on radiograph that occur in the same location, both during illness and when well (see Chapter 395.4). Traction bronchiectasis may also be suggested on radiography with persistent findings in a given region of the film following history of respiratory infection. Particular attention must be directed to the possibility that the infiltrates represent lymphocytic interstitial pneumonitis or opportunistic infection associated with HIV infection (see Chapter 276). A history of paroxysmal coughing in an infant suggests pertussis syndrome or cystic fibrosis. Persistent infiltrates, especially with loss of volume, in a toddler should suggest foreign-body aspiration.

Overinflation and infiltrates suggest cystic fibrosis or chronic asthma. A "silent chest" with infiltrates should arouse suspicion of alveolar proteinosis (see Chapter 405), *Pneumocystis jiroveci* infection (see Chapter 244), genetic disorders of surfactant synthesis and secretion causing interstitial pneumonitis, or tumors. Growth should be carefully assessed to determine whether the lung process has had systemic effects, indicating substantial severity and chronicity as in cystic fibrosis or alveolar proteinosis. Cataracts, retinopathy, or microcephaly suggest in utero infection. Chronic rhinorrhea can be associated with atopic disease, cow's milk intolerance, cystic fibrosis, or congenital syphilis. The absence of tonsils and cervical lymph nodes suggests an immunodeficiency state.

Diagnostic studies should be performed selectively, based on information obtained from history and physical examination and on a thorough understanding of the conditions listed in Table 384-6. Cytologic evaluation of sputum, if available, may be helpful. Chest CT often provides more precise anatomic detail concerning the infiltrate or further characterize a region of anatomic abnormality. Bronchoscopy is indicated for detecting foreign bodies, congenital or acquired anomalies of the tracheobronchial tract, and obstruction by endobronchial or extrinsic masses (see Chapter 394). Bronchoscopy provides access to secretions that can be studied cytologically and microbiologically. Alveolar lavage fluid is diagnostic for alveolar proteinosis and persistent pulmonary hemosiderosis and can suggest aspiration syndromes. If all appropriate studies have been completed and the condition remains undiagnosed, lung biopsy might yield a definitive diagnosis, such as in interstitial lung disease or in fungal disease.

Optimal medical or surgical treatment of chronic lung infiltrates often depends on a specific diagnosis, but chronic conditions may be self-limiting (severe and prolonged viral infections in infants); in these cases, symptomatic therapy can maintain adequate lung function until spontaneous improvement occurs. Helpful measures include inhalation and physical therapy for excessive secretions, antibiotics for bacterial infections, supplementary oxygen for hypoxemia, and maintenance of adequate nutrition. Because the lung of a young child has remarkable recuperative potential, normal lung function may ultimately be achieved with treatment despite the severity of pulmonary insult occurring in infancy or early childhood.

Chapter 385

Acute Inflammatory Upper Airway Obstruction (Croup, Epiglottitis, Laryngitis, and Bacterial Tracheitis)

Genie E. Roosevelt

Airway resistance is inversely proportional to the 4th power of the radius (see Chapter 373). Because the lumen of an infant's or child's airway is narrow, minor reductions in cross-sectional area as a result of mucosal edema or other inflammatory processes cause an exponential increase in airway resistance and a significant increase in the work of breathing. The larynx is composed of 4 major cartilages (**epiglottic**, **arytenoid**, **thyroid**, and **cricoid cartilages**, ordered from superior to inferior) and the soft tissues that surround them. The cricoid cartilage encircles the airway just below the vocal cords and defines the narrowest portion of the upper airway in children younger than 10 yr of age.

Inflammation involving the vocal cords and structures inferior to the cords is called **laryngitis, laryngotracheitis**, or **laryngotracheobronchitis**, and inflammation of the structures superior to the cords (i.e., arytenoids, aryepiglottic folds ["false cords"], epiglottis) is called **supraglottitis**. The term **croup** refers to a heterogeneous group of mainly acute and infectious processes that are characterized by a bark-like or brassy cough and may be associated with hoarseness, inspiratory stridor, and respiratory distress. **Stridor** is a harsh, high-pitched respiratory sound, which is usually inspiratory but can be biphasic and is produced by turbulent airflow; it is not a diagnosis but a sign of upper airway obstruction (see Chapter 374). Croup typically affects the larynx, trachea, and bronchi. When the involvement of the larynx is sufficient to produce symptoms, they dominate the clinical picture over the tracheal and bronchial signs. A distinction has been made between spasmodic or recurrent croup and laryngotracheobronchitis. Some clinicians believe that spasmodic croup might have an allergic component and improves rapidly without treatment, whereas laryngotracheobronchitis is always associated with a viral infection of the respiratory tract. Others believe that the signs and symptoms are similar enough to consider them within the spectrum of a single disease, in part because studies have documented viral etiologies in both acute and recurrent croup.

385.1 Infectious Upper Airway Obstruction

Genie E. Roosevelt

ETIOLOGY AND EPIDEMIOLOGY

With the exceptions of diphtheria (see Chapter 187), bacterial tracheitis, and epiglottitis, most acute infections of the upper airway are caused by viruses. The parainfluenza viruses (types 1, 2, and 3; see Chapter 259) account for approximately 75% of cases; other viruses

associated with croup include influenza A and B, adenovirus, respiratory syncytial virus, and measles. Influenza A is associated with severe laryngotracheobronchitis. *Mycoplasma pneumoniae* has rarely been isolated from children with croup and causes mild disease (see Chapter 223). Most patients with croup are between the ages of 3 mo and 5 yr, with the peak in the 2nd yr of life. The incidence of croup is higher in boys. It occurs most commonly in the late fall and winter but can occur throughout the year. Recurrences are frequent from 3-6 yr of age and decrease with growth of the airway. Approximately 15% of patients have a strong family history of croup.

In the past, *Haemophilus influenzae* type b was the most commonly identified etiology of acute epiglottitis. Since the widespread use of the *H. influenzae* type b vaccine, invasive disease caused by *H. influenzae* type b in pediatric patients has been reduced by 99% (see Chapter 194). Therefore, other agents, such as *Streptococcus pyogenes, Streptococcus pneumoniae,* nontypeable *H. influenzae*, and *Staphylococcus aureus,* represent a larger portion of pediatric cases of epiglottitis in vaccinated children. In the prevaccine era, the typical patient with epiglottitis caused by *H. influenzae* type b was 2-4 yr of age, although cases were seen in the 1st yr of life and in patients as old as 7 yr of age. Currently, the most common presentation of epiglottitis is an adult with a sore throat, although cases still do occur in underimmunized children; vaccine failures have been reported.

Figure 385-1 Radiograph of an airway of a patient with croup, showing typical subglottic narrowing (steeple sign).

CLINICAL MANIFESTATIONS

Croup (Laryngotracheobronchitis)

Viruses typically cause croup, the most common form of acute upper respiratory obstruction. The term **laryngotracheobronchitis** refers to viral infection of the glottic and subglottic regions. Some clinicians use the term **laryngotracheitis** for the most common and most typical form of croup and reserve the term **laryngotracheobronchitis** for the more severe form that is considered an extension of laryngotracheitis associated with bacterial superinfection that occurs 5-7 days into the clinical course.

Most patients have an upper respiratory tract infection with some combination of rhinorrhea, pharyngitis, mild cough, and low-grade fever for 1-3 days before the signs and symptoms of upper airway obstruction become apparent. The child then develops the characteristic "barking" cough, hoarseness, and inspiratory stridor. The low-grade fever can persist, although temperatures may occasionally reach 39-40°C (102.2-104°F); some children are afebrile. Symptoms are characteristically worse at night and often recur with decreasing intensity for several days and resolve completely within a week. Agitation and crying greatly aggravate the symptoms and signs. The child may prefer to sit up in bed or be held upright. Older children usually are not seriously ill. Other family members might have mild respiratory illnesses with laryngitis. Most young patients with croup progress only as far as stridor and slight dyspnea before they start to recover.

Physical examination can reveal a hoarse voice, coryza, normal to moderately inflamed pharynx, and a slightly increased respiratory rate. Patients vary substantially in their degrees of respiratory distress. Rarely, the upper airway obstruction progresses and is accompanied by an increasing respiratory rate; nasal flaring; suprasternal, infrasternal, and intercostal retractions; and continuous stridor. Croup is a disease of the upper airway, and alveolar gas exchange is usually normal. Hypoxia and low oxygen saturation are seen only when complete airway obstruction is imminent. **The child who is hypoxic, cyanotic, pale, or obtunded needs immediate airway management.** Occasionally, the pattern of severe laryngotracheobronchitis is difficult to differentiate from epiglottitis, despite the usually more acute onset and rapid course of the latter.

Croup is a clinical diagnosis and does not require a radiograph of the neck. Radiographs of the neck can show the typical subglottic narrowing, or steeple sign, of croup on the posteroanterior view (Fig. 385-1). However, the steeple sign may be absent in patients with croup, may be present in patients without croup as a normal variant, and may rarely be present in patients with epiglottitis. The radiographs do not correlate well with disease severity. Radiographs should be considered only after airway stabilization in children who have an atypical presentation or clinical course. Radiographs may be helpful in distinguishing between severe laryngotracheobronchitis and epiglottitis, but airway management should always take priority.

Acute Epiglottitis (Supraglottitis)

This now rare, but still dramatic and potentially lethal condition is characterized by an acute rapidly progressive and potentially fulminating course of high fever, sore throat, dyspnea, and rapidly progressing respiratory obstruction. The degree of respiratory distress at presentation is variable. The initial lack of respiratory distress can deceive the unwary clinician; respiratory distress can also be the first manifestation. Often, the otherwise healthy child suddenly develops a sore throat and fever. Within a matter of hours, the patient appears toxic, swallowing is difficult, and breathing is labored. Drooling is usually present and the neck is hyperextended in an attempt to maintain the airway. The child may assume the tripod position, sitting upright and leaning forward with the chin up and mouth open while bracing on the arms. A brief period of air hunger with restlessness may be followed by rapidly increasing cyanosis and coma. Stridor is a late finding and suggests near-complete airway obstruction. Complete obstruction of the airway and death can ensue unless adequate treatment is provided. The barking cough typical of croup is rare. Usually, no other family members are ill with acute respiratory symptoms.

The diagnosis requires visualization under controlled circumstances of a large, cherry red, swollen epiglottis by laryngoscopy. Occasionally, the other supraglottic structures, especially the aryepiglottic folds, are more involved than the epiglottis itself. In a patient in whom the diagnosis is certain or probable based on clinical grounds, laryngoscopy should be performed expeditiously in a controlled environment such as an operating room or intensive care unit. Anxiety-provoking interventions such as phlebotomy, intravenous line placement, placing the child supine, or direct inspection of the oral cavity should be avoided until the airway is secure. If epiglottitis is thought to be possible but not certain in a patient with acute upper airway obstruction, the patient may undergo lateral radiographs of the upper airway first. Classic radiographs of a child who has epiglottitis show the thumb sign (Fig. 385-2). Proper positioning of the patient for the lateral neck radiograph is crucial in order to avoid some of the pitfalls associated with interpretation of the film. Adequate hyperextension of the head and neck is necessary. In addition, the epiglottis can appear to be round if the lateral neck is taken at an oblique angle. If the concern for epiglottitis still exists after the radiographs, direct visualization should be performed. A physician skilled in airway management and use of

Figure 385-2 Lateral roentgenogram of the upper airway reveals the swollen epiglottis (thumb sign).

intubation equipment should accompany patients with suspected epiglottitis at all times. An older cooperative child might voluntarily open the mouth wide enough for a direct view of the inflamed epiglottis.

Establishing an airway by endotracheal or nasotracheal intubation or, less often, by tracheostomy is indicated in patients with epiglottitis, regardless of the degree of apparent respiratory distress, because as many as 6% of children with epiglottitis without an artificial airway die, compared with <1% of those with an artificial airway. No clinical features have been recognized that predict mortality. Pulmonary edema can be associated with acute airway obstruction. The duration of intubation depends on the clinical course of the patient and the duration of epiglottic swelling, as determined by frequent examination using direct laryngoscopy or flexible fiberoptic laryngoscopy. In general, children with acute epiglottitis are intubated for 2-3 days, because the response to antibiotics is usually rapid. Most patients have concomitant bacteremia; occasionally, other infections are present, such as pneumonia, cervical adenopathy, or otitis media. Meningitis, arthritis, and other invasive infections with *H. influenzae* type b are rarely found in conjunction with epiglottitis.

Acute Infectious Laryngitis

Laryngitis is a common illness. Viruses cause most cases; diphtheria is an exception but is extremely rare in industrialized countries (see Chapter 187). The onset is usually characterized by an upper respiratory tract infection during which sore throat, cough, and hoarseness appear. The illness is generally mild; respiratory distress is unusual except in the young infant. Hoarseness and loss of voice may be out of proportion to systemic signs and symptoms. The physical examination is usually not remarkable except for evidence of pharyngeal inflammation. Inflammatory edema of the vocal cords and subglottic tissue may be demonstrated laryngoscopically. The principal site of obstruction is usually the subglottic area.

Spasmodic Croup

Spasmodic croup occurs most often in children 1-3 yr of age and is clinically similar to acute laryngotracheobronchitis, except that the history of a viral prodrome and fever in the patient and family are often absent. The cause is viral in some cases, but allergic and psychologic factors may be important in others.

Occurring most commonly in the evening or nighttime, spasmodic croup begins with a sudden onset that may be preceded by mild to moderate coryza and hoarseness. The child awakens with a characteristic barking, metallic cough, noisy inspiration, and respiratory distress and appears anxious and frightened. The patient is usually afebrile. The severity of the symptoms generally diminishes within several hr, and the following day, the patient often appears well except for slight hoarseness and cough. Similar, but usually less severe, attacks without extreme respiratory distress can occur for another night or two. Such episodes often recur several times. Spasmodic croup might represent more of an allergic reaction to viral antigens than direct infection, although the pathogenesis is unknown.

DIFFERENTIAL DIAGNOSIS

These 4 syndromes must be differentiated from one another and from a variety of other entities that can present as upper airway obstruction. **Bacterial tracheitis** is the most important differential diagnostic consideration and has a high risk of airway obstruction. Diphtheritic croup is extremely rare in North America, although a major epidemic of diphtheria occurred in countries of the former Soviet Union beginning in 1990 from the lack of routine immunization. Early symptoms of diphtheria include malaise, sore throat, anorexia, and low-grade fever. Within 2-3 days, pharyngeal examination reveals the typical gray-white membrane, which can vary in size from covering a small patch on the tonsils to covering most of the soft palate. The membrane is adherent to the tissue, and forcible attempts to remove it cause bleeding. The course is usually insidious, but respiratory obstruction can occur suddenly. Measles croup almost always coincides with the full manifestations of systemic disease and the course may be fulminant (see Chapter 246).

Sudden onset of respiratory obstruction can be caused by aspiration of a **foreign body** (see Chapter 387). The child is usually 6 mo-3 yr of age. Choking and coughing occur suddenly, usually without prodromal signs of infection, although children with a viral infection can also aspirate a foreign body. A **retropharyngeal** or **peritonsillar abscess** can mimic respiratory obstruction (see Chapter 382). CT scans of the upper airway are helpful in evaluating the possibility of a retropharyngeal abscess. A peritonsillar abscess is a clinical diagnosis. Other possible causes of upper airway obstruction include extrinsic compression of the airway (laryngeal web, vascular ring) and intraluminal obstruction from masses (laryngeal papilloma, subglottic hemangioma); these tend to have chronic or recurrent symptoms.

Upper airway obstruction is occasionally associated with **angioedema** of the subglottic areas as part of anaphylaxis and generalized allergic reactions, edema after endotracheal intubation for general anesthesia or respiratory failure, hypocalcemic tetany, infectious mononucleosis, trauma, and tumors or malformations of the larynx. A croupy cough may be an early sign of asthma. Vocal cord dysfunction can also occur. Epiglottitis, with the characteristic manifestations of drooling or dysphagia and stridor, can also result from the accidental ingestion of very hot liquid.

COMPLICATIONS

Complications occur in approximately 15% of patients with viral croup. The most common is extension of the infectious process to involve other regions of the respiratory tract, such as the middle ear, the terminal bronchioles, or the pulmonary parenchyma. Bacterial tracheitis may be a complication of viral croup rather than a distinct disease. If associated with *S. aureus or S. pyogenes,* toxic shock syndrome can develop. Bacterial tracheitis may have a 2-phased illness, with the 2nd phase after a croup-like illness associated with high fever, toxicity, and airway obstruction. Alternatively, the onset of tracheitis occurs without a 2nd phase and appears as a continuation of the initial croup-like illness but with higher fever and worsening respiratory distress rather than the usual recovery after 2-3 days of viral croup. Pneumonia, cervical lymphadenitis, otitis media, or, rarely, meningitis or septic arthritis can occur in the course of epiglottitis. Pneumomediastinum and pneumothorax are the most common complications of tracheotomy.

TREATMENT

The mainstay of treatment for children with **croup** is airway management and treatment of hypoxia. Treatment of the respiratory distress

should take priority over any testing. Most children with either acute spasmodic croup or infectious croup can be managed safely at home. Despite the observation that cold night air is beneficial, a Cochrane review has found no evidence supporting the use of cool mist in the emergency department for the treatment of croup.

Nebulized racemic epinephrine is an accepted treatment for moderate or severe croup. The mechanism of action is believed to be constriction of the precapillary arterioles through the β-adrenergic receptors, causing fluid resorption from the interstitial space and a decrease in the laryngeal mucosal edema. Traditionally, racemic epinephrine, a 1 : 1 mixture of the D- and L-isomers of epinephrine, has been administered. A dose of 0.25-0.5 mL of 2.25% racemic epinephrine in 3 mL of normal saline can be used as often as every 20 min. Racemic epinephrine was initially chosen over the more active and more readily available L-epinephrine to minimize anticipated cardiovascular side effects such as tachycardia and hypertension. There is evidence that L-epinephrine (5 mL of 1 : 1,000 solution) is equally effective as racemic epinephrine and does not carry the risk of additional adverse effects.

The indications for the administration of nebulized epinephrine include moderate to severe **stridor at rest,** the possible need for intubation, respiratory distress, and hypoxia. The duration of activity of racemic epinephrine is <2 hr. Consequently, observation is mandated. The symptoms of croup might reappear, but racemic epinephrine does not cause rebound worsening of the obstruction. Patients can be safely discharged home after a 2-3 hr period of observation provided they have no stridor at rest; have normal air entry, normal pulse oximetry, and normal level of consciousness; and have received steroids. Nebulized epinephrine should still be used cautiously in patients with tachycardia, heart conditions such as tetralogy of Fallot, or ventricular outlet obstruction because of possible side effects.

The effectiveness of **oral corticosteroids** in viral croup is well established. Corticosteroids decrease the edema in the laryngeal mucosa through their antiinflammatory action. Oral steroids are beneficial, even in mild croup, as measured by reduced hospitalization, shorter duration of hospitalization, and reduced need for subsequent interventions such as epinephrine administration. Most studies that demonstrated the efficacy of oral dexamethasone used a *single dose of 0.6 mg/kg*, a dose as low as 0.15 mg/kg may be just as effective. Intramuscular dexamethasone and nebulized budesonide have an equivalent clinical effect; oral dosing of dexamethasone is as effective as intramuscular administration. A single dose of oral prednisolone is less effective. There are no controlled studies examining the effectiveness of multiple doses of corticosteroids. The only adverse effect in the treatment of croup with corticosteroids is the development of *Candida albicans* laryngotracheitis in a patient who received dexamethasone, 1 mg/kg/24 hr, for 8 days. Corticosteroids should not be administered to children with varicella or tuberculosis (unless the patient is receiving appropriate antituberculosis therapy) because they worsen the clinical course.

Antibiotics are not indicated in croup. Nonprescription cough and cold medications should not be used in children younger than 4 yr of age. A helium-oxygen mixture (heliox) may be considered in the treatment of children with severe croup for whom intubation is being considered although the evidence is inconclusive. Children with croup should be hospitalized for any of the following: progressive stridor, severe stridor at rest, respiratory distress, hypoxia, cyanosis, depressed mental status, poor oral intake, or the need for reliable observation.

Epiglottitis is a medical emergency and warrants immediate treatment with an **artificial airway** placed under controlled conditions, either in an operating room or intensive care unit. All patients should receive oxygen en route unless the mask causes excessive agitation. Racemic epinephrine and corticosteroids are ineffective. Cultures of blood, epiglottic surface, and, in selected cases, cerebrospinal fluid should be collected after the airway is stabilized. *Cefotaxime*, *ceftriaxone,* or *meropenem* should be given parenterally, pending culture and susceptibility reports, because 10-40% of *H. influenzae* type b cases are resistant to ampicillin. After insertion of the artificial airway, the patient should improve immediately, and respiratory distress and cyanosis should disappear. Epiglottitis resolves after a few days of antibiotics, and the patient may be extubated; antibiotics should be continued for at least 10 days. Chemoprophylaxis is not routinely recommended for household, childcare, or nursery contacts of patients with invasive *H. influenzae* type b infections, but careful observation is mandatory, with prompt medical evaluation when exposed children develop a febrile illness. **Indications for rifampin prophylaxis** (20 mg/kg orally once a day for 4 days; maximum dose: 600 mg) for all household members include a child within the home who is younger than 4 yr of age and incompletely immunized, younger than 12 mo of age and has not completed the primary vaccination series, or immunocompromised.

Acute laryngeal swelling on an allergic basis responds to epinephrine (1 : 1,000 dilution in dosage of 0.01 mL/kg to a maximum of 0.5 mL/dose) administered intramuscularly or racemic epinephrine (dose of 0.5 mL of 2.25% racemic epinephrine in 3 mL of normal saline) (see Chapter 149). Corticosteroids are often required (1-2 mg/kg/24 hr of prednisone for 3-5 days). After recovery, the patient and parents should be discharged with a preloaded syringe of epinephrine to be used in emergencies. Reactive mucosal swelling, severe stridor, and respiratory distress unresponsive to mist therapy may follow endotracheal intubation for general anesthesia in children. Racemic epinephrine and corticosteroids are helpful.

Endotracheal/Nasotracheal Intubation and Tracheotomy

With the introduction of routine intubation or, less often, tracheotomy for epiglottitis, the mortality rate for epiglottis has dropped to almost zero. These procedures should always be performed in an operating room or intensive care unit if time permits; prior intubation and general anesthesia greatly facilitate performing a tracheotomy without complications. The use of an endotracheal or nasotracheal tube that is 0.5-1.0 mm smaller than estimated by age or height is recommended to facilitate intubation and reduce long-term sequelae. The choice of procedure should be based on the local expertise and experience with the procedure and postoperative care.

Intubation or tracheotomy is required for most patients with bacterial tracheitis and all young patients with epiglottitis. It is rarely required for patients with laryngotracheobronchitis, spasmodic croup, or laryngitis. Severe forms of laryngotracheobronchitis that require intubation in a high proportion of patients have been reported during severe measles and influenza A virus epidemics. Assessing the need for these procedures requires experience and judgment because they should not be delayed until cyanosis and extreme restlessness have developed (see Chapter 71). As with epiglottitis, an endotracheal or nasotracheal tube that is 0.5-1.0 mm smaller than estimated by age or height is recommended.

The endotracheal tube or tracheostomy must remain in place until edema and spasm have subsided and the patient is able to handle secretions satisfactorily. It should be removed as soon as possible, usually within a few days. Adequate resolution of epiglottic inflammation that has been accurately confirmed by fiberoptic laryngoscopy, permitting much more rapid extubation, often occurs within 24 hr. Racemic epinephrine and dexamethasone (0.5 mg/kg/dose 6-12 hr prior to extubation then every 6 hr for 6 doses with a maximum dose of 10 mg) may be useful in the treatment of upper airway edema seen postintubation.

PROGNOSIS

In general, the length of hospitalization and the mortality rate for cases of acute infectious upper airway obstruction increase as the infection extends to involve a greater portion of the respiratory tract, except in epiglottitis, in which the localized infection itself can prove to be fatal. Most deaths from croup are caused by a laryngeal obstruction or by the complications of tracheotomy. Rarely, fatal out-of-hospital arrests caused by viral laryngotracheobronchitis have been reported, particularly in infants and in patients whose course has been complicated by bacterial tracheitis. Untreated epiglottitis has a mortality rate of 6% in some series, but if the diagnosis is made and appropriate treatment is initiated before the patient is moribund, the prognosis is excellent. The

outcome of acute laryngotracheobronchitis, laryngitis, and spasmodic croup is also excellent.

Bibliography is available at Expert Consult.

385.2 Bacterial Tracheitis

Genie E. Roosevelt

Bacterial tracheitis is an acute bacterial infection of the upper airway that is potentially life threatening. *S. aureus* (see Chapter 181) is the most commonly isolated pathogen with isolated reports of methicillin-resistant *S. aureus*. *S. pneumoniae*, *S. pyogenes*, *Moraxella catarrhalis*, nontypeable *H. influenzae*, and anaerobic organisms have also been implicated. The mean age is between 5 and 7 yr. There is a slight male predominance. Bacterial tracheitis often follows a viral respiratory infection (especially laryngotracheitis), so it may be considered a bacterial complication of a viral disease, rather than a primary bacterial illness. This life-threatening entity is more common than epiglottitis in vaccinated populations.

CLINICAL MANIFESTATIONS

Typically, the child has a brassy cough, apparently as part of a viral laryngotracheobronchitis. High fever and "toxicity" with respiratory distress can occur immediately or after a few days of apparent improvement. The patient can lie flat, does not drool, and does not have the dysphagia associated with epiglottitis. The usual treatment for croup (racemic epinephrine) is ineffective. Intubation or tracheostomy may be necessary, but only 50-60% of patients require intubation for management; younger patients are more likely to need intubation. The major pathologic feature appears to be mucosal swelling at the level of the cricoid cartilage, complicated by copious, thick, purulent secretions, sometimes causing pseudomembranes. Suctioning these secretions, although occasionally affording temporary relief, usually does not sufficiently obviate the need for an artificial airway.

DIAGNOSIS

The diagnosis is based on evidence of bacterial upper airway disease, which includes high fever, purulent airway secretions, and an absence of the classic findings of epiglottitis. X-rays are not needed but can show the classic findings (Fig. 385-3); purulent material is noted below the cords during endotracheal intubation (Fig. 385-4).

TREATMENT

Appropriate antimicrobial therapy, which usually includes antistaphylococcal agents, should be instituted in any patient whose course suggests bacterial tracheitis. Current empiric therapy recommendations for bacterial tracheitis include vancomycin or clindamycin and a third-generation cephalosporin (e.g., cefotaxime or ceftriaxone). When bacterial tracheitis is diagnosed by direct laryngoscopy or is strongly

suspected on clinical grounds, an artificial airway should be strongly considered. Supplemental oxygen is usually necessary.

COMPLICATIONS

Chest radiographs often show patchy infiltrates and may show focal densities. Subglottic narrowing and a rough and ragged tracheal air column can often be demonstrated radiographically. If airway management is not optimal, cardiorespiratory arrest can occur. Toxic shock syndrome has been associated with staphylococcal and group A streptococcal tracheitis (see Chapter 181.2).

PROGNOSIS

The prognosis for most patients is excellent. Patients usually become afebrile within 2-3 days of the institution of appropriate antimicrobial therapy, but prolonged hospitalization may be necessary. In recent years, there appears to be a trend toward a less-morbid condition. With a decrease in mucosal edema and purulent secretions, extubation can be accomplished safely, and the patient should be observed carefully while antibiotics and oxygen therapy are continued.

Chapter 386
Congenital Anomalies of the Larynx, Trachea, and Bronchi

James W. Schroeder Jr. and Lauren D. Holinger

The larynx functions as a breathing passage, a valve to protect the lungs, and the primary organ of communication; symptoms of laryngeal anomalies are those of airway obstruction, difficulty feeding, and abnormalities of phonation (see Chapter 373). Obstructive congenital lesions of the upper airway produce turbulent airflow according to the laws of fluid dynamics. This rapid, turbulent airflow across a narrowed segment of respiratory tract produces distinctive sounds that are diagnostically useful to the clinician. The timing of noisy breathing in relation to the sleep–wake cycle is important. Obstruction of the pharyngeal airway (by enlarged tonsils, adenoids, tongue, or syndromes with midface hypoplasia) typically produces worse obstruction during sleep than during waking. Obstruction that is worse when awake is typically laryngeal, tracheal, or bronchial, and is exacerbated by exertion. The location of the obstruction dictates the respiratory phase, tone and nature of the sound and these qualities direct the differential diagnosis. Intrathoracic lesions typically cause expiratory wheezing and stridor, often masquerading as asthma. The expiratory wheezing contrasts to the inspiratory stridor caused by the extrathoracic lesions of congenital laryngeal anomalies, specifically laryngomalacia and bilateral vocal cord paralysis. Stridor describes the low-pitched inspiratory snoring sound typically produced by nasal or nasopharyngeal obstruction.

With airway obstruction, the severity of the obstructing lesion, the work of breathing, determines the necessity for diagnostic procedures and surgical intervention. Obstructive symptoms vary from mild to severe stridor with episodes of apnea, cyanosis, suprasternal (tracheal tugging) and subcostal retractions, dyspnea, and tachypnea. Congenital anomalies of the trachea and bronchi can create serious respiratory difficulties from the 1st few min of life. Chronic obstruction can cause failure to thrive.

Bibliography is available at Expert Consult.

386.1 Laryngomalacia

James W. Schroeder Jr. and Lauren D. Holinger

CLINICAL MANIFESTATIONS

Laryngomalacia is the most common congenital laryngeal anomaly and the most common cause of stridor in infants and children. Sixty percent of congenital laryngeal anomalies in children with stridor are due to laryngomalacia. Stridor is inspiratory, low-pitched, and exacerbated by any exertion: crying, agitation, or feeding. The stridor is caused, in part, by decreased laryngeal tone leading to supraglottic collapse during inspiration. Symptoms usually appear within the 1st 2 wk of life and increase in severity for up to 6 mo, although gradual improvement can begin at any time. Gastroesophageal reflux disease and neurologic disease influence the severity of the disease and thereby the clinical course.

DIAGNOSIS

The diagnosis is made primarily based on symptoms. The diagnosis is confirmed by outpatient flexible laryngoscopy (Fig. 386-1). When the work of breathing is moderate to severe, airway films and chest radiographs are indicated. Laryngomalacia can contribute to feeding difficulties and dysphagia in some children because of decreased laryngeal sensation and poor suck swallow breath coordination. When the inspiratory stridor sounds wet or is associated with a cough or when there is a history of repeat upper respiratory illness or pneumonia, dysphagia should be considered. When dysphagia is suspected, a contrast swallow study and/or a fiberoptic endoscopic evaluation of swallowing esophagram may be considered. Because 15-60% of infants with laryngomalacia have synchronous airway anomalies, complete bronchoscopy is undertaken for patients with moderate to severe obstruction.

TREATMENT

Expectant observation is suitable for most infants because most symptoms resolve spontaneously as the child and airway grow.

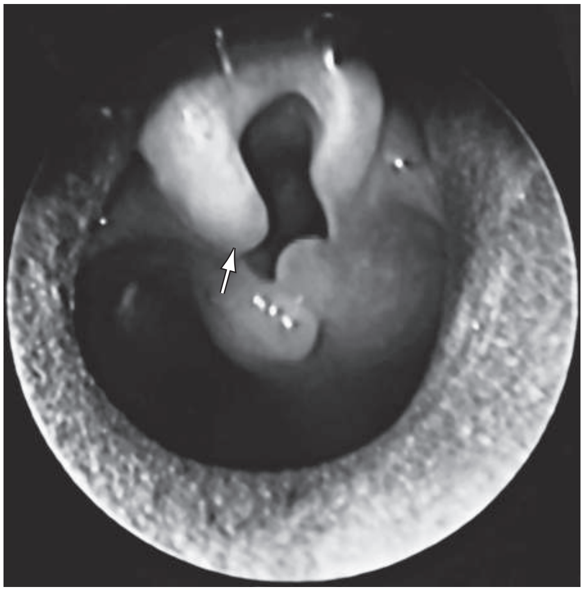

Figure 386-1 Endoscopic example of laryngomalacia. On inspiration, the epiglottic folds collapse into the airway. The lateral tips of the epiglottis are also collapsing inward *(arrow). (From Slovis TL, editor:* Caffey's pediatric diagnostic imaging, *ed 11, Philadelphia, 2008, Mosby.)*

Bibliography

Zoumalan R, Maddalozzo J, Holinger LD: Etiology of stridor in infants, *Ann Otol Rhinol Laryngol* 116:329–334, 2007.

Laryngopharyngeal reflux is managed aggressively. In 15-20% of patients symptoms are severe enough to cause progressive respiratory distress, cyanosis, or failure to thrive. In these patients surgical intervention via supraglattoplasty is considered. Supraglattoplasty is 90% successful in relieving upper airway obstruction caused by laryngomalacia.

Bibliography is available at Expert Consult.

386.2 Congenital Subglottic Stenosis

James W. Schroeder Jr. and Lauren D. Holinger

CLINICAL MANIFESTATIONS

Congenital subglottic stenosis is the second most common cause of stridor. The subglottis is the narrowest part of the upper airway in a child. Subglottic stenosis is a narrowing of the subglottic larynx, which is the space extending from the undersurface of the true vocal cords to the inferior margin of the cricoid cartilage. It typically causes respiratory distress and biphasic or primarily inspiratory stridor. It may be congenital or acquired. Symptoms often occur with a respiratory tract infection as the edema and thickened secretions of a common cold narrow an already compromised airway leading to recurrent or persistent croup like symptoms.

Biphasic or primarily inspiratory stridor is the typical presenting symptom for congenital subglottic stenosis. Recurrent or persistent croup usually occurs in these children at 6 mo of age or younger. The edema and thickened secretions of the common cold further narrow an already marginal airway that leads to croup-like symptoms. The stenosis can be caused by an abnormally shaped cricoid cartilage; by a tracheal ring that becomes trapped underneath the cricoid cartilage; or by soft tissue thickening caused by ductal cysts, submucosal gland hyperplasia or fibrosis.

DIAGNOSIS

The diagnosis made by airway radiographs is confirmed by direct laryngoscopy. During diagnostic laryngoscopy the subglottic larynx is visualized directly and sized objectively using endotracheal tubes (Fig. 386-2). The percentage of stenosis is determined by comparing the size of the patients' larynx to a standard of laryngeal dimensions based on age. Stenosis >50% is usually symptomatic and often requires treatment. As with all cases of upper airway obstruction, tracheostomy is avoided when possible. Dilation and endoscopic laser surgery are rarely effective because most congenital stenoses are cartilaginous. Anterior laryngotracheal decompression (cricoid split) or laryngotracheal reconstruction with cartilage grafting is usually effective in avoiding tracheostomy. The differential diagnosis includes other anatomic anomalies as well as a hemangioma or papillomatosis.

Bibliography is available at Expert Consult.

386.3 Vocal Cord Paralysis

James W. Schroeder Jr. and Lauren D. Holinger

CLINICAL MANIFESTATIONS

Vocal cord paralysis is the third most common congenital laryngeal anomaly that produces stridor in infants and children. Congenital central nervous system lesions such as myelomeningocele, Chiari malformation, and hydrocephalus may be associated with bilateral paralysis.

Unilateral vocal cord paralysis is most often iatrogenic as a result of surgical treatment for gastrointestinal (tracheoesophageal fistula) and cardiovascular (patent ductus arteriosis repair) anomalies. Bilateral vocal cord paralysis produces airway obstruction manifested by high-pitched inspiratory stridor: a phonatory sound or inspiratory cry. Unilateral paralysis causes aspiration, coughing, and choking; the cry is weak and breathy, but stridor and other symptoms of airway obstruction are less common.

DIAGNOSIS

The diagnosis of vocal cord paralysis is made by awake flexible laryngoscopy. A thorough investigation for the underlying primary cause is indicated. Because of the association with other congenital lesions, evaluation includes neurology and cardiology consultations as well as diagnostic endoscopy of the larynx, trachea, and bronchi.

TREATMENT

Treatment is based on the severity of the symptoms. Vocal cord paralysis in infants usually resolves spontaneously within 6-12 mo. If it does not resolve within 2-3 yr, it is unlikely to do so. Bilateral paralysis can require temporary tracheotomy. Procedures that widen the posterior glottis to relieve the obstruction include laryngotracheal reconstruction using an endoscopically placed posterior glottis cartilage graft, or arytenoidectomy, or arytenoid lateralization. These procedures are successful in reducing the obstruction. However, they may result in aspiration that may become severe. For unilateral vocal cord paralysis with aspiration, injection laterally to the paralyzed vocal cord moves it medially to reduce aspiration and related complications.

386.4 Congenital Laryngeal Webs and Atresia

James W. Schroeder Jr. and Lauren D. Holinger

Most congenital laryngeal webs are glottic with subglottic extension and associated subglottic stenosis. Chromosomal and cardiovascular anomalies as well as chromosome 22 q 11 deletion are common in patients with congenital laryngeal web. Airway obstruction is not always present and may be related to the subglottic stenosis. Thick webs may be suspected in lateral radiographs of the airway. Diagnosis is made by direct laryngoscopy (Fig. 386-3). Treatment might require only incision or dilation. Webs with associated subglottic stenosis are likely to require cartilage augmentation of the cricoid cartilage (laryngotracheal reconstruction). Laryngeal atresia occurs as a complete glottic web and commonly is associated with tracheal agenesis and tracheoesophageal fistula.

386.5 Congenital Subglottic Hemangioma

James W. Schroeder Jr. and Lauren D. Holinger

Symptoms of airway obstruction typically occur within the 1st 2 mo. of life. Stridor is biphasic but usually more prominent during inspiration. A barking cough, hoarseness, and symptoms of recurrent or persistent croup are typical. Only 1% of children who have cutaneous hemangiomas will have a subglottic hemangioma. However, 50% of those with a subglottic hemangioma will have a cutaneous hemangioma. A facial hemangioma is not always present, but when it is evident, it is in the beard distribution. Chest and neck radiographs can show the characteristic asymmetric narrowing of the subglottic larynx. Treatment is discussed in Chapter 390.3.

Bibliography is available at Expert Consult.

386.6 Laryngoceles and Saccular Cysts

James W. Schroeder Jr. and Lauren D. Holinger

A laryngocele is an abnormal air-filled dilation of the laryngeal saccule that arises vertically between the false vocal cord, the base of the epiglottic and the inner surface of the thyroid cartilage. It communicates with the laryngeal lumen and, when intermittently filled with air, causes hoarseness and dyspnea. A saccular cyst (congenital cyst of the larynx) is distinguished from the laryngocele in that its lumen is isolated from the interior of the larynx and it contains mucus, not air in infants and children, laryngoceles cause hoarseness and dyspnea that may increase with crying. Saccular cysts may cause respiratory distress and stridor. A saccular cyst may be visible on radiography, but the diagnosis is made by laryngoscopy (Fig. 386-4). Needle aspiration of the cyst confirms the diagnosis but rarely provides a cure. Approaches include endoscopic CO_2 laser excision, endoscopic extended ventriculotomy (marsupialization or unroofing), or, traditionally, external excision.

Bibliography is available at Expert Consult.

386.7 Posterior Laryngeal Cleft and Laryngotracheoesophageal Cleft

James W. Schroeder Jr. and Lauren D. Holinger

The posterior laryngeal cleft is characterized by aspiration and is the result of a deficiency in the midline of the posterior larynx. Posterior laryngeal clefts are categorized into 4 types. Type 1 clefts are mild and the interarytenoid notch only extends down to the level of the true vocal cords; 60% of these will cause no symptoms and will not require surgical repair. In severe cases, the cleft (type 4) extends inferiorly into the cervical or thoracic trachea so there is no separation between the trachea and esophagus, creating a laryngotracheoesophageal cleft. Laryngeal clefts can occur in families and are likely to be associated with tracheal agenesis, tracheoesophageal fistula, and multiple congenital anomalies, as with G syndrome, Opitz-Frias syndrome, and Pallister-Hall syndrome.

Initial symptoms are those of aspiration and recurrent respiratory infections. Esophagogram is undertaken with extreme caution. Confirmation of the diagnosis is made by direct laryngoscopy and bronchoscopy. Treatment is based on the cleft type and the symptoms. Stabilization of the airway is the first priority. Gastroesophageal reflux must be controlled and a careful assessment for other congenital anomalies is undertaken before repair. Several endoscopic and open cervical and transthoracic surgical repairs have been described.

Bibliography is available at Expert Consult.

386.8 Vascular and Cardiac Anomalies

James W. Schroeder Jr. and Lauren D. Holinger

The aberrant innominate artery is the most common cause of secondary tracheomalacia (see Chapter 432). It may be asymptomatic and discovered incidentally or it may cause severe symptoms. Expiratory wheezing and cough occur and, rarely, reflex apnea or "dying spells." Surgical intervention is rarely necessary. Infants are treated expectantly because the problem is self-limited.

The term *vascular ring* is used to describe vascular anomalies that result from abnormal development of the aortic arch complex. The double aortic arch is the most common complete vascular ring, encircling both the trachea and esophagus, compressing both. With few exceptions, these patients are symptomatic by 3 mo of age. Respiratory symptoms predominate, but dysphagia may be present. The diagnosis is established by barium esophagram that shows a posterior indentation of the esophagus by the vascular ring (see Fig. 432-2 in Chapter 432). CT scan with contrast or MRI with angiography provides the surgeon the information needed.

Other vascular anomalies include the pulmonary artery sling, which also requires surgical correction. The most common open (incomplete) vascular ring is the aberrant right subclavian artery. Although common, it is usually asymptomatic and of academic interest only.

Congenital cardiac defects are likely to compress the left main bronchus or lower trachea. Any condition that produces significant pulmonary hypertension increases the size of the pulmonary arteries, which in turn cause compression of the left main bronchus. Surgical correction of the underlying pathology to relieve pulmonary hypertension relieves the airway compression.

Bibliography is available at Expert Consult.

386.9 Tracheal Stenoses, Webs, and Atresia

James W. Schroeder Jr. and Lauren D. Holinger

Long-segment congenital tracheal stenosis with complete tracheal rings typically occurs within the 1st yr of life, usually after a crisis has been precipitated by an acute respiratory illness. The diagnosis may be suggested by plain radiographs. CT with contrast delineates associated intrathoracic anomalies such as the pulmonary artery sling, which occurs in one third of patients; one fourth have associated cardiac anomalies. Bronchoscopy is the best method to define the degree and extent of the stenosis and the associated abnormal bronchial branching pattern. Treatment of clinically significant stenosis involves tracheal resection of short segment stenosis, slide tracheoplasty for long segment stenosis. Congenital soft-tissue stenoses and thin webs are rare. Dilation may be all that is required.

Bibliography is available at Expert Consult.

386.10 Foregut Cysts

James W. Schroeder Jr. and Lauren D. Holinger

The bronchogenic cyst, intramural esophageal cyst (esophageal duplication), and enteric cyst can all produce symptoms of respiratory obstruction and dysphagia. The diagnosis is suspected when chest radiographs or CT scan delineate the mass, and, in the case of enteric cyst, the associated vertebral anomaly. The treatment of all foregut cysts is surgical excision.

Chapter 387

Foreign Bodies in the Airway

James W. Schroeder Jr. and Lauren D. Holinger

EPIDEMIOLOGY AND ETIOLOGY

Choking is a leading cause of morbidity and mortality among children, especially those younger than age 4 yr, largely because of the developmental vulnerabilities of a young child's airway and the underdeveloped ability to swallow food. Infants and toddlers use their mouths to explore their surroundings. Most victims of foreign-body aspiration are older infants and toddlers (Fig. 387-1). Children, younger than 3 yr of age, account for 73% of cases. Preambulatory toddlers can aspirate objects given to them by older siblings. The most common objects that children choke on are food, coins, balloons, and toys. One-third of aspirated objects are nuts, particularly peanuts. Fragments of raw carrot, apple, dried beans, popcorn, and sunflower or watermelon seeds are also aspirated, as are small toys or toy parts. Hard candy and chewing gum are also commonly involved objects. Adolescents may aspirate objects put in their mouth such as pins, jewelry, or blowgun darts. From 1972-1992, 449 deaths from aspirated nonfood foreign bodies among children were reported by the United States Consumer Product Safety Commission. An infant is developmentally able to suck and swallow and also is equipped with involuntary reflexes (gag, cough, and glottis closure) that help to protect against aspiration during swallowing. Dentition develops at approximately 6 mo with eruption of the incisors. Molars do not erupt until approximately 1.5 yr of age; however, mature mastication takes longer to develop. Despite a strong gag reflex, a young child's airway is more vulnerable to obstruction than an adult's airway in several ways. The smaller diameter is more likely to experience significant blockage by small foreign bodies. Mucous and secretions may form a seal around the foreign body, making it more difficult to dislodge by forced air. In addition, the force of air generated by a cough in an infant or young child is less effective in dislodging an airway obstruction. The American Academy of Pediatrics recommends that children younger than 5 yr old should avoid hard candy, chewing gum and that raw fruits and vegetables be cut into small pieces.

The most serious complication of foreign-body aspiration is complete obstruction of the airway. Globular or round food objects such

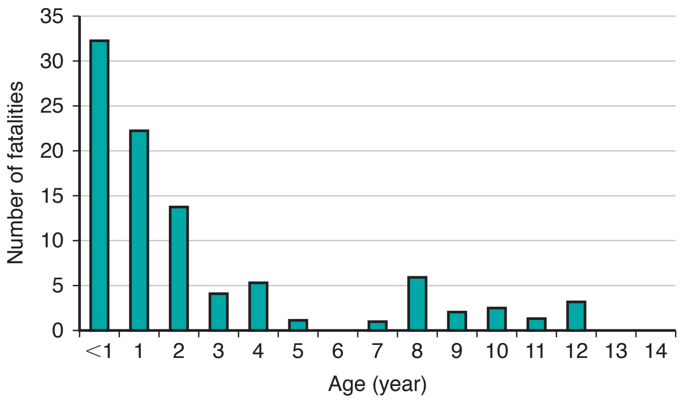

Figure 387-1 Number of fatalities vs victim age, all fatality types. *(From Milkovich SM, Altkorn R, Chen X, et al: Development of the small parts cylinder: lessons learned,* Laryngoscope *118[11]:2082–2086, 2008.)*

as hot dogs, grapes, nuts, and candies are the most frequent offenders. Hot dogs are rarely seen as airway foreign bodies because toddlers who choke on hot dogs asphyxiate at the scene unless treated immediately. Complete airway obstruction is recognized in the conscious child as sudden respiratory distress followed by inability to speak or cough.

CLINICAL MANIFESTATIONS

Three stages of symptoms may result from aspiration of an object into the airway:

1. **Initial event:** Violent paroxysms of coughing, choking, gagging, and possibly airway obstruction occur immediately when the foreign body is aspirated.
2. **Asymptomatic interval:** The foreign body becomes lodged, reflexes fatigue, and the immediate irritating symptoms subside. This stage is most treacherous and accounts for a large percentage of delayed diagnoses and overlooked foreign bodies. It is during this 2nd stage, when the child is first seen, that the possibility of a foreign-body aspiration is minimized, the physician being reassured by the absence of symptoms that no foreign body is present.
3. **Complications:** Obstruction, erosion, or infection develops to direct attention again to the presence of a foreign body. In this 3rd stage, complications include fever, cough, hemoptysis, pneumonia, and atelectasis.

DIAGNOSIS

A positive history must never be ignored. A negative history may be misleading. Choking or coughing episodes accompanied by new onset wheezing are highly suggestive of an airway foreign body. Because nuts are the most common bronchial foreign body, the physician specifically questions the toddler's parents about nuts. If there is any history of eating nuts, bronchoscopy is carried out promptly.

Most airway foreign bodies lodge in a bronchus (right bronchus ~58% of cases); the location is the larynx or trachea in approximately 10% of cases. Occasionally, fragments of a foreign body may produce bilateral involvement or shifting infiltrates if it moves from lobe to lobe. An esophageal foreign body can compress the trachea and be mistaken for an airway foreign body. The patient is asymptomatic and the radiograph is normal in 15-30% of cases. Opaque foreign bodies occur in only 10-25% of cases. CT can help define radiolucent foreign bodies such as fish bones. If there is a high index of suspicion, bronchoscopy should be performed despite negative imaging studies. History is the most important factor in determining the need for bronchoscopy.

TREATMENT

The treatment of choice for airway foreign bodies is prompt endoscopic removal with rigid instruments. Bronchoscopy is deferred only until preoperative studies have been obtained and the patient has been prepared by adequate hydration and emptying of the stomach. Airway foreign bodies are usually removed the same day the diagnosis is first considered.

387.1 Laryngeal Foreign Bodies

James W. Schroeder Jr. and Lauren D. Holinger

Complete obstruction asphyxiates the child unless it is promptly relieved with the Heimlich maneuver (see Chapter 67 and Figs. 67-6 and 67-7). Objects that are partially obstructive are usually flat and thin. They lodge between the vocal cords in the sagittal plane, causing symptoms of croup, hoarseness, cough, stridor, and dyspnea.

387.2 Tracheal Foreign Bodies

James W. Schroeder Jr. and Lauren D. Holinger

Choking and aspiration occurs in 90% of patients with tracheal foreign bodies, stridor in 60%, and wheezing in 50%. Posteroanterior and lateral soft tissue neck radiographs (airway films) are abnormal in 92% of children, whereas chest radiographs are abnormal in only 58%.

387.3 Bronchial Foreign Bodies

James W. Schroeder Jr. and Lauren D. Holinger

Posteroanterior and lateral chest radiographs are standard in the assessment of infants and children suspected of having aspirated a foreign object. The abdomen is included. A good expiratory posteroanterior chest film is most helpful. During expiration the bronchial foreign body obstructs the exit of air from the obstructed lung, producing obstructive emphysema, air trapping, with persistent inflation of the obstructed lung and shift of the mediastinum toward the opposite side (Fig. 387-2). Air trapping is an immediate complication, in contrast to atelectasis, which is a late finding. Lateral decubitus chest films

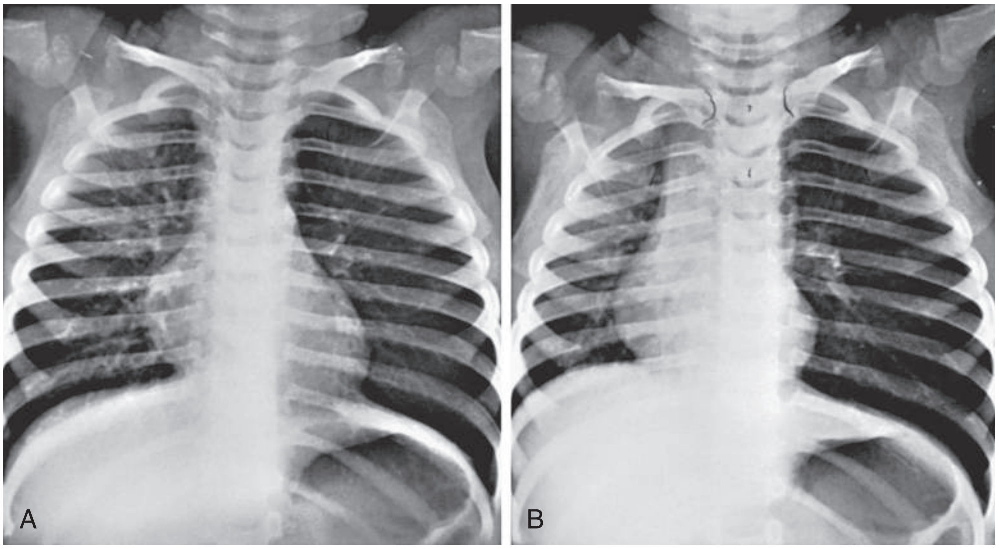

Figure 387-2 **A,** Normal inspiratory chest radiograph in a toddler with a peanut fragment in the left main bronchus. **B,** Expiratory radiograph of the same child showing the classic obstructive emphysema (air trapping) on the involved (left) side. Air leaves the normal right side allowing the lung to deflate. The medium shifts toward the unobstructed side.

or fluoroscopy can provide the same information but are unnecessary. History and physical examination, not radiographs, determine the indication for bronchoscopy.

Chapter 388

Laryngotracheal Stenosis and Subglottic Stenosis

James W. Schroeder Jr. and Lauren D. Holinger

Laryngotracheal stenosis is the second most common cause of stridor in neonates and is the most common cause of airway obstruction requiring tracheostomy in infants. The glottis (vocal cords) and the upper trachea are also compromised in most laryngeal stenoses, particularly those that develop following endotracheal intubation. Subglottic stenosis is a narrowing of the subglottic larynx, which is the space extending from the undersurface of the true vocal cords to the inferior margin of the cricoid cartilage. Subglottic stenosis is considered to be congenital when there is no other apparent cause such as a history of laryngeal trauma; approximately 90% of cases manifest in the 1st yr of life.

388.1 Congenital Subglottic Stenosis

See Chapter 386.2.

388.2 Acquired Laryngotracheal Stenosis

James W. Schroeder Jr. and Lauren D. Holinger

Ninety percent of acquired stenoses are associated with endotracheal intubation, although with improved ventilatory support, the incidence of this complication is decreasing. Studies published after 1983 reported an incidence of neonatal subglottic stenosis of <4%, and those after 1990 reported an incidence of <0.63%. When the pressure of the endotracheal tube against the mucosa is greater than the capillary pressure, ischemia occurs, followed by necrosis and ulceration. Secondary infection and perichondritis develop with exposure of cartilage. Granulation tissue forms around the ulcerations (Fig. 388-1). These changes and edema throughout the larynx usually resolve spontaneously after extubation. Chronic edema and fibrous stenosis develop in only a small percentage of cases. A number of factors predispose to the development of laryngeal stenosis. Laryngopharyngeal reflux of acid and pepsin from the stomach exacerbates endotracheal tube trauma. More damage is caused in areas left unprotected, owing to loss of mucosa. Congenital subglottic stenosis narrows the larynx which makes the patient more likely to develop acquired subglottic stenosis because significant injury is more likely to occur with use of an endotracheal tube of age-appropriate size. Other risk factors for the development of acquired subglottic stenosis include sepsis and infection, dehydration, malnutrition, chronic inflammatory disorders, and immunosuppression. An oversized endotracheal tube is the most common factor contributing to laryngeal injury. A tube that allows a small air leak at the end of the inspiratory cycle minimizes potential trauma. Other extrinsic factors—traumatic intubation, multiple reintubations, movement of the endotracheal tube, and duration of intubation—can contribute to varying degrees in individual patients.

Figure 388-1 Laryngoscopy in 6 mo old infant 4 hr after extubation showing granulation in subglottic region. *(From Smith MM, Kuhl G, Carvalho PR, Marostica PJ: Flexible fiber-optic laryngoscopy in the first hours after extubation for the evaluation of laryngeal lesions due to intubation in the pediatric intensive care unit.* Int J Pediatr Otorhinolaryngol *71(9):1423–1428, 2007, Fig. 4.)*

CLINICAL MANIFESTATIONS

Symptoms of acquired and congenital stenosis are similar. Spasmodic croup, the sudden onset of severe croup in the early morning hours, is usually caused by laryngopharyngeal reflux with transient laryngospasm and subsequent laryngeal edema. These frightening episodes resolve rapidly, often before the family and child reach the emergency department.

DIAGNOSIS

The diagnosis can be made by posteroanterior and lateral airway radiographs and is confirmed by direct laryngoscopy and bronchoscopy. High-resolution CT imaging is of limited value. This is similar to the work-up associated with congenital subglottic stenosis.

TREATMENT

The severity, location, and type (cartilaginous or soft tissue) of the stenosis determine the treatment. Mild cases can be managed without operative intervention because the airway will improve as the child grows. Moderate soft-tissue stenosis is treated by endoscopy using gentle dilations or CO_2 laser. Severe laryngotracheal stenosis is likely to require laryngotracheal expansion surgery or resection of the narrowed portion of the laryngeal and tracheal airway (partial cricotracheal resection). Every effort is made to avoid tracheotomy using endoscopic techniques or open surgical procedures.

Chapter 389

Bronchomalacia and Tracheomalacia

Jonathan D. Finder

Tracheomalacia and bronchomalacia refer to chondromalacia of a central airway, leading to insufficient cartilage to maintain airway patency throughout the respiratory cycle. These are common causes of persistent wheezing in infancy. Tracheomalacia and bronchomalacia can be either primary or secondary (Table 389-1). Primary tracheomalacia and bronchomalacia are often seen in premature infants, although most affected patients are born at term. Secondary tracheomalacia and bronchomalacia refers to the situation in which the central airway is compressed by adjacent structure (e.g., vascular ring; see Chapter 432) or deficient in cartilage because of tracheoesophageal fistula (see Chapter 319). Laryngomalacia can accompany primary bronchomalacia or tracheomalacia. Involvement of the entire central airway (laryngotracheobronchomalacia) is also seen.

CLINICAL MANIFESTATIONS

Primary tracheomalacia and bronchomalacia are principally disorders of infants, with a male : female ratio of 2 : 1. The dominant finding, low-pitched monophonic wheezing heard predominantly during expiration, is most prominent over the central airways. Parents often describe persistent respiratory congestion even in the absence of a viral respiratory infection. When the lesion involves only 1 main bronchus (more commonly the left), the wheezing is louder on that side, and there may be unilateral palpable fremitus. In cases of tracheomalacia, the wheeze is loudest over the trachea. Hyperinflation and/or subcostal retractions do not occur unless the patient also has concurrent asthma, viral bronchiolitis, or other causes of peripheral airways obstruction. In the absence of asthma, patients with tracheomalacia and bronchomalacia are not helped by administration of a bronchodilator. Acquired tracheomalacia and bronchomalacia are seen in association with vascular compression (vascular rings, slings, and innominate artery compression). Tracheomalacia is the rule following correction of tracheoesophageal fistula. Other causes of acquired tracheomalacia, which may persist after surgical correction, are cardiomegaly. Bronchomalacia is common following lung transplantation, assumed to be secondary to the loss of bronchial artery supply leading to hypoxia of the cartilage. The importance of the physical exam cannot be understated; 1 study found that pediatric pulmonologists made a correct assessment of malacia based on symptoms, history, and lung function prior to bronchoscopy in 74% of cases.

Table 389-1	Classification of Tracheomalacia
PRIMARY TRACHEOMALACIA Congenital absence of tracheal-supporting cartilages	
SECONDARY TRACHEOMALACIA Esophageal atresia, tracheoesophageal fistula Vascular rings (double aortic arch) Tracheal compression from an aberrant innominate artery Tracheal compression from mediastinal masses Abnormally soft tracheal cartilages associated with connective tissue disorders Prolonged mechanical ventilation, chronic lung disease	

From McNamara VM, Crabbe DC: Tracheomalacia, Paediatr Respir Rev *5:147–154, 2004.*

DIAGNOSIS

Definitive diagnoses of tracheomalacia and bronchomalacia are established by flexible or rigid bronchoscopy (Fig. 389-1). The lesion is difficult to detect on plain radiographs. While fluoroscopy can demonstrate dynamic collapse and avoid the need for invasive diagnostic techniques, it is poorly sensitive. Pulmonary function testing can show a pattern of decreased peak flow and flattening of the flow-volume loop. Other important diagnostic modalities include MRI and CT scanning. MRI with angiography is especially useful when there is a possibility of vascular ring and should be performed when a right aortic arch is seen on plain film radiography.

TREATMENT

Postural drainage can help with clearance of secretions. β-Adrenergic agents should be avoided in the absence of asthma, because they can exacerbate loss of airway patency due to decreased airway tone. Nebulized ipratropium bromide may be useful. Endobronchial stents have been used in severely affected patients but have a high incidence of complications, ranging from airway obstruction due to granulation tissue to erosion into adjacent vascular structures. Continuous positive airway pressure via tracheostomy may be indicated for severe cases. Surgical approach (aortopexy and bronchopexy) is rarely required and only for patients who have life-threatening apnea, cyanosis, and bradycardia (“cyanotic spells”) from airway obstruction, and/or who demonstrated vascular compression.

PROGNOSIS

Primary bronchomalacia and tracheomalacia have excellent prognoses, because airflow improves as the child and the airways grow. Patients with primary airway malacia usually take longer to recover from common respiratory infections. Wheezing at rest usually resolves

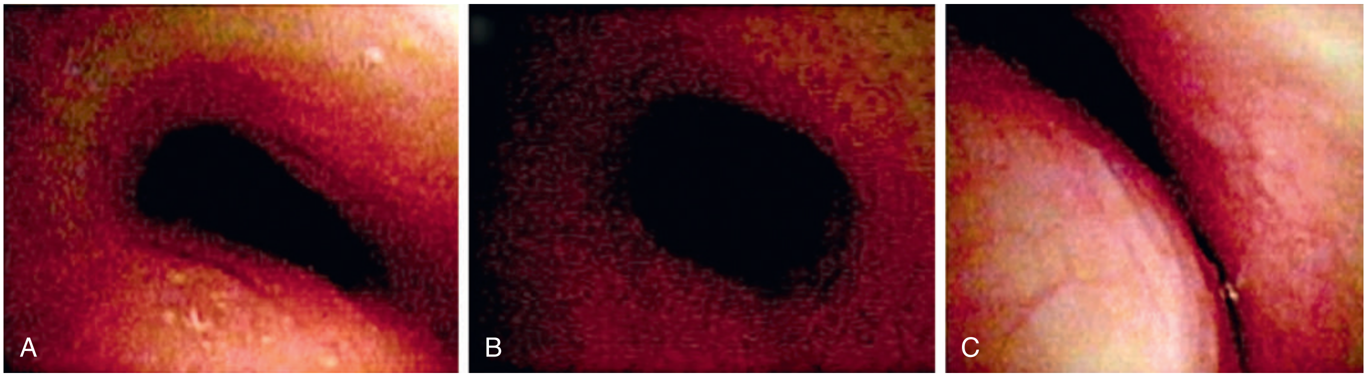

Figure 389-1 Images of tracheomalacia taken 10 mm from site. **A,** Saber-shaped or triangular appearance. **B,** Circumferential appearance. **C,** Crescent (lunate) appearance. *(From Masters IB, Zimmerman PV, Pandeya N, et al: Quantified tracheobronchomalacia disorders and their clinical profiles in children,* Chest *133:461–467, 2008.)*

by age 3 yr. Prolonged bacterial bronchitis has been reported as a complication of bronchomalacia. Prognosis in secondary and acquired forms varies with cause. Patients with concurrent asthma need considerable supportive treatment and careful monitoring of respiratory status.

Chapter 390
Neoplasms of the Larynx, Trachea, and Bronchi

390.1 Vocal Nodules

James W. Schroeder Jr. and Lauren D. Holinger

Vocal nodules, which are not true neoplasms, are the most common cause of chronic hoarseness in children. Chronic vocal abuse or misuse produces nodules at the junction of the anterior and middle thirds of the phonating edge of the vocal cords. These symmetric, bilateral swellings interfere with voice production and cause children to strain the voice. Vocal nodules can occur in infants.

When vocal abuse is the main factor, the voice is worse in the evenings. Voice therapy may be effective in the cooperative child, but for most toddlers and young children, behavioral therapy is necessary. Nodules usually resolve by early teenage years as the child matures and vocal abuse is moderated. Surgical excision is rarely indicated but may be necessary if the child is unable to communicate adequately, becomes aphonic, or requires tension and straining to make any utterance whatsoever.

When laryngopharyngeal reflux is the main factor, hoarseness is worse in the morning; laryngopharyngeal reflux commonly exacerbates vocal abuse, adding to swelling of the vocal cords. An antireflux regimen is indicated (see Chapter 323.1).

390.2 Recurrent Respiratory Papillomatosis

James W. Schroeder Jr. and Lauren D. Holinger

Papillomas are the most common respiratory tract neoplasms in children, occurring in 4.3 in 100,000. They are simply warts—benign tumors—caused by the human papillomavirus (HPV) (see Chapter 266); the same pathology is found in condylomata acuminata (vaginal warts). HPV types 6 and 11 are most commonly associated with laryngeal disease. Although it is a benign disease that usually involves the larynx, recurrent respiratory papillomatosis (RRP) has a predictable clinical course, tends to recur and spread throughout the aerodigestive tract and can undergo malignant conversion. Fifty percent of recurrent RRP cases occur in children younger than age 5 yr, but the diagnosis may be made at any age; 67% of children with RRP are born to mothers who had condylomata during pregnancy or parturition. The mode of HPV transmission is still not clear. The risk for transmission is approximately 1 in 500 vaginal births in mothers with active condylomata. Neonates have been reported to have RRP, suggesting intrauterine transmission of HPV.

CLINICAL MANIFESTATIONS

These benign squamous lesions can produce chronic hoarseness in the infant. Most occur in the larynx, specifically on the vocal cords, but in 31% these lesions occur in other areas of the respiratory tract: nose, pharynx (especially the uvula and posterior soft palate), trachea, bronchi, and lungs. As growth of the lesions on the vocal cords progresses, hoarseness increases and communication becomes difficult. Respiratory distress develops. Surgical excision is a quality of life issue that warrants removal to improve the voice. Intervention becomes a medical necessity when airway obstruction progresses (Fig. 390-1). Symptoms often occur first during sleep with symptoms typical of obstructive sleep apnea. Progressive respiratory distress during sleep, exertion, daily activities, and finally at rest indicates the need for surgical intervention.

Figure 390-1 Laryngoscopic view of respiratory papillomas causing near complete obstruction at glottic level. *(From Derkay CS, Wiatrak B: Recurrent respiratory papillomatosis: a review,* Laryngoscope *118: 1236–1245, 2008.)*

TREATMENT

The treatment of RRP is endoscopic surgical removal. Most surgeons in North America prefer the microdébrider. Laryngopharyngeal reflux can require treatment when reflux laryngitis is a factor. Although surgical management remains the mainstay therapy, some form of adjunct therapy may be needed in up to 20% of cases. The most widely accepted indications for adjunct therapy are a need for more than 4 surgical procedures per year, rapid regrowth of papillomata with airway compromise, or distal multisite spread of disease. Adjunct therapies include antiviral modalities (interferon, ribavirin, acyclovir, cidofovir), photodynamic therapy, dietary supplement (indole-3-carbinol), nonsteroidal antiinflammatory drug (Celebrex), retinoids, and mumps vaccination.

Bibliography is available at Expert Consult.

390.3 Congenital Subglottic Hemangioma

James W. Schroeder Jr. and Lauren D. Holinger

CLINICAL MANIFESTATIONS

Typically, congenital subglottic hemangiomas are symptomatic within the 1st 2 mo of life, almost all occurring before 6 mo of age. Stridor is biphasic but usually more prominent during inspiration. The infant may be hoarse, have a barking cough, and present with croup. Fifty percent of congenital subglottic hemangiomas are associated with facial lesions. Radiographs classically delineate an asymmetric subglottic narrowing. The diagnosis is made by direct laryngoscopy.

TREATMENT

The treatment of hemangiomas often requires input from a multispecialty vascular anomalies team. Medical management includes systemic steroids. Prednisone 2-4 mg/kg/day is given orally for 4-6 wk, less if the lesions stabilize sooner. The dosage is then tapered. If there is no response, the drug is discontinued. Propranolol 2-3 mg/kg/day is

emerging as a first-line treatment for hemangiomas with the potential to impair function (airway) or cause disfigurement if there are no cardiac or neurovascular contraindications. Although the exact mechanism of action of propranolol is unknown, it has been shown to stop progression and induce involution of hemangiomas in multiple studies. Because side effects include hypotension, bradycardia, bronchospasm, and hypoglycemia, children treated with propranolol need to be monitored closely.

Although tracheostomy establishes a safe airway, every effort should be made to find an alternative. Corticosteroids can also be injected directly into the lesion. Endoscopic excision with the CO_2 laser is effective. Combining several modalities increases the possibility of avoiding tracheotomy. External surgical excision is suitable for some lesions.

Bibliography is available at Expert Consult.

390.4 Vascular Anomalies

James W. Schroeder Jr. and Lauren D. Holinger

Vascular malformations are not true neoplastic lesions. They have a normal rate of endothelial turnover and various channel abnormalities. They are categorized by their predominant type (capillary, venous, arterial, lymphatic, or a combination thereof). Slow-flow malformations have capillary, lymphatic, or venous components. In the past, these were incorrectly called capillary hemangiomas, cystic hygromas or lymphangiomas, and cavernous hemangiomas, respectively.

Lymphatic malformations (cystic hygromas) rarely occur in the larynx. When they do, they are invariably an extension of disease from elsewhere in the head and neck. Airway obstruction can necessitate tracheostomy. The lesion can be debulked with the CO_2 laser.

Bibliography is available at Expert Consult.

390.5 Other Laryngeal Neoplasms

James W. Schroeder Jr. and Lauren D. Holinger

Neurofibromatosis (see Chapter 596.1) rarely involves the larynx. When children are affected, limited local resection is undertaken to maintain an airway and optimize the voice. Complete surgical extirpation is virtually impossible without debilitating resection of vital laryngeal structures. Most surgeons select the option of less-aggressive symptomatic surgery because of the poorly circumscribed and infiltrative nature of these fibromas. **Rhabdomyosarcoma** (see Chapter 500) and other malignant tumors of the larynx are rare. Symptoms of hoarseness and progressive airway obstruction prompt initial evaluation by flexible laryngoscopy in the office.

390.6 Tracheal Neoplasms

James W. Schroeder Jr. and Lauren D. Holinger

Tracheal tumors include malignant and benign neoplasms. The 2 most common benign tumors are inflammatory pseudotumor and hamartoma. The **inflammatory pseudotumor** is probably a reaction to a previous bronchial infection or traumatic insult. Growth is slow and the tumor may be locally invasive. Hamartomas are tumors of primary tissue elements that are abnormal in proportion and arrangement.

Tracheal neoplasms manifest with stridor, wheezing, cough, or pneumonia and are rarely diagnosed until 75% of the lumen has been obstructed (Fig. 390-2). Symptoms mimic asthma and are often misdiagnosed as such. Chest radiographs or airway films can identify the obstruction. Pulmonary function studies demonstrate an abnormal flow-volume loop. A mild response to bronchodilator therapy may be misleading. Rational treatment is based upon the histopathology.

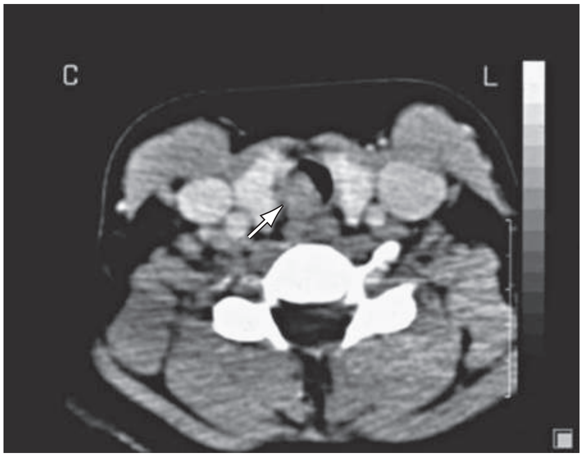

Figure 390-2 A CT scan of the trachea with a circumscribed intraluminal tracheal mass *(arrow)* in the tracheal wall. *(From Venizelos I, Papathomas T, Anagnostou E, et al: Pediatric inflammatory myofibroblastic tumor of the trachea: a case report and review of the literature,* Pediatr Pulmonol *43:831–835, 2008.)*

390.7 Bronchial Tumors

James W. Schroeder Jr. and Lauren D. Holinger

Bronchial tumors are rare. Two-thirds are malignant. Bronchial "adenomas" are the most common, representing 30% of all lung tumors. Bronchogenic carcinoma is the second most common and occurs in approximately 20% of cases. Bronchial carcinoid also occurs. The diagnosis is confirmed at bronchoscopy and biopsy; treatment depends on the histopathology.

Chapter 391 Wheezing, Bronchiolitis, and Bronchitis

391.1 Wheezing in Infants: Bronchiolitis

Bria M. Coates, Lauren E. Camarda, and Denise M. Goodman

DEFINITIONS AND GENERAL PATHOPHYSIOLOGY

Wheezing, the production of a musical and continuous sound that originates from oscillations in narrowed airways, is heard mostly on expiration as a result of critical airway obstruction. **Monophonic** wheezing refers to a single-pitch sound that is produced in the larger airways during expiration, as in distal tracheomalacia or bronchomalacia. Wheezing is **polyphonic** when there is widespread narrowing of the airways, causing various pitches as air moves through different levels of obstruction to flow, as seen in asthma. When obstruction occurs in the extrathoracic airways during inspiration, the noise is referred to as **stridor.**

Infants are more likely to wheeze than older children and adults as a result of a differing set of lung mechanics. The obstruction to flow is affected by the airway caliber and compliance of the infant lung. Resistance to airflow through a tube is inversely related to the radius of the tube to the 4th power. In children younger than 5 yr old, small-caliber

peripheral airways can contribute up to 50% of the total airway resistance. Marginal additional narrowing can cause further flow limitation and a subsequent wheeze.

With the very compliant newborn chest wall, the inward pressure produced in expiration subjects the intrathoracic airways to collapse. Differences in tracheal cartilage composition and airway smooth muscle tone increase the collapsibility of the infant airways in comparison to older children. These mechanisms combine to make the infant more susceptible to airway obstruction, increased resistance, and subsequent wheezing. Many of these conditions are outgrown in the 1st yr of life.

Immunologic and molecular influences can contribute to the infant's propensity to wheeze. In comparison to older children and adults, infants tend to have higher levels of lymphocytes and neutrophils, rather than mast cells and eosinophils, in bronchoalveolar lavage fluid. The childhood wheezing phenotype has been linked to many early exposures including fetal nutrition, maternal smoking, prenatal and birth maternal complications, prenatal and neonatal exposure to antibiotics, exposure to high levels of environmental allergens, and high infant adiposity. Infections during infancy have been cited as risk factors for later wheezing, including respiratory syncytial virus (RSV; see Chapter 260), rhinovirus (see Chapter 263), cytomegalovirus (see Chapter 255), human metapneumovirus (see Chapter 261), bocavirus, adenovirus, and *Chlamydia pneumoniae*.

A variety of inflammatory mediators have also been implicated in the wheezing infant such as histamine, cytokines, leukotrienes, and interleukins. Taken together, these fetal and/or early postnatal exposures may cause a "programming" of the lung that ultimately affects structure and function.

ETIOLOGY

Although wheezing in infants most frequently results from inflammation (generally bronchiolitis), there are many causes of wheezing (Table 391-1).

Acute Bronchiolitis and Inflammation of the Airway

Infection can cause obstruction to flow by internal narrowing of the airways.

Acute bronchiolitis is predominantly a viral disease. RSV is responsible for more than 50% of cases. Other agents include parainfluenza, adenovirus, rhinovirus, and *Mycoplasma*. Emerging pathogens include human metapneumovirus and human bocavirus, which may be a primary cause of viral respiratory infection or occur as a coinfection with RSV. Although bacterial pneumonia is sometimes confused clinically with bronchiolitis, there is no evidence of a bacterial cause for bronchiolitis and bronchiolitis is rarely followed by bacterial superinfection. Concurrent infection with viral bronchiolitis and pertussis has been described.

Approximately 100,000-126,000 children younger than 1 yr old are hospitalized annually in the United States because of RSV infection. The increasing rates of bronchiolitis that were seen from 1980-1996 (thought to reflect increased attendance of infants in daycare centers, changes in criteria for hospital admission, and/or improved survival of premature infants and others at risk for severe RSV-associated disease), have not continued. In fact, rates have stayed stable in subsequent years despite introduction and routine use of RSV immunoprophylaxis in high-risk populations.

Bronchiolitis is more common in boys, in those who have not been breastfed, and in those who live in crowded conditions. Risk is higher for infants with young mothers or mothers who smoked during pregnancy. Older family members are a common source of infection; they might only experience minor upper respiratory symptoms (colds). The clinical manifestations of lower respiratory tract illness seen in young infants may be minimal in older patients, in whom bronchiolar edema is better tolerated.

Not all infected infants develop lower respiratory tract illness. Host anatomic and immunologic factors play a significant role in the severity of the clinical syndrome, as does the nature of the viral pathogen.

Table 391-1	Differential Diagnosis of Wheezing in Infancy
INFECTION	
Viral	
Respiratory syncytial virus	
Human metapneumovirus

Bronchopulmonary dysplasia	
Interstitial lung disease, including bronchiolitis obliterans	
Heart failure	
Anaphylaxis	
Inhalation injury—burns	

Infants with preexistent smaller airways and diminished lung function have a more severe course. In addition, RSV infection incites a complex immune response. Eosinophils degranulate and release eosinophil cationic protein, which is cytotoxic to airway epithelium. Innate immunity plays a significant role and can depend on polymorphisms in toll-like receptors, interferons, interleukins, and nuclear factor κB. Chemokines and cytokines, such as tumor necrosis factor α, may be differentially expressed, depending on the inciting virus. Coinfection with more than 1 virus can also alter the clinical manifestations and/or severity of presentation.

Acute bronchiolitis is characterized by bronchiolar obstruction with edema, mucus, and cellular debris. Even minor bronchiolar wall thickening significantly affects airflow because resistance is inversely proportional to the 4th power of the radius of the bronchiolar passage. Resistance in the small air passages is increased during both inspiration and exhalation, but because the radius of an airway is smaller during expiration, the resultant respiratory obstruction leads to early air trapping and overinflation. If obstruction becomes complete, trapped distal air will be resorbed and the child will develop atelectasis.

Hypoxemia is a consequence of ventilation–perfusion mismatch early in the course. With severe obstructive disease and tiring of respiratory effort, hypercapnia can develop.

Chronic infectious causes of wheezing should be considered in infants who seem to fall out of the range of a normal clinical course. Cystic fibrosis is one such entity; suspicion increases in a patient with persistent respiratory symptoms, digital clubbing, malabsorption, failure to thrive, electrolyte abnormalities, or a resistance to bronchodilator treatment (see Chapter 403).

Allergy and asthma are important causes of wheezing and probably generate the most questions by the parents of a wheezing infant. Asthma is characterized by airway inflammation, bronchial hyperreactivity, and reversibility of obstruction (see Chapter 144). Three identified patterns of infant wheezing are the transient early wheezer, the persistent wheezer, and the late-onset wheezer. These patterns are seen in 19.9%, 13.7%, and 15% of the general population, respectively, with the remaining 50% of the population never wheezing prior to age 6 yr. Transient early wheezers wheeze at least once with a lower respiratory infection before the age of 3 yr, but never wheeze again. The persistent wheezer has wheezing episodes before age 3 yr and is still wheezing at 6 yr of age. The late-onset wheezer does not wheeze before age 3 yr but is wheezing by 6 yr. Of all the infants who wheezed before 3 yr old, almost 60% stopped wheezing by age 6 yr.

Multiple studies have tried to predict which early wheezers will go on to have asthma in later life. Risk factors for persistent wheezing include parental history of asthma and allergies, maternal smoking, persistent rhinitis (apart from acute upper respiratory tract infections), allergen sensitization, eczema at younger than 1 yr of age, peripheral eosinophilia (>4%), and frequent episodes of wheezing during infancy.

Other Causes

Congenital malformations of the respiratory tract cause wheezing in early infancy. These findings can be diffuse or focal and can be from an external compression or an intrinsic abnormality. *External vascular compression* includes a vascular ring, in which the trachea and esophagus are surrounded completely by vascular structures, or a vascular sling, in which the trachea and esophagus are not completely encircled (see Chapter 432). *Cardiovascular causes* of wheezing include dilated chambers of the heart including massive cardiomegaly, left atrial enlargement, and dilated pulmonary arteries. Pulmonary edema caused by heart failure can also cause wheezing by lymphatic and bronchial vessel engorgement that leads to obstruction and edema of the bronchioles and further obstruction (see Chapter 442).

Foreign-body aspiration (see Chapter 397) can cause acute or chronic wheezing. It is estimated that 78% of those who die from foreign-body aspiration are between 2 mo and 4 yr old. Even in young infants, a foreign body can be ingested if given to the infant by another person, such as an older sibling. Infants who have atypical histories or misleading clinical and radiologic findings can receive a misdiagnosis of asthma or another obstructive disorder as inflammation and granulation develop around the foreign body. An esophageal foreign body can transmit pressure to the membranous trachea, causing compromise of the airway lumen.

Gastroesophageal reflux (see Chapter 323.1) can cause wheezing with or without direct aspiration into the tracheobronchial tree. Without aspiration, the reflux is thought to trigger a vagal or neural reflex, causing increased airway resistance and airway reactivity. Aspiration from gastroesophageal reflux or from the direct aspiration from oral liquids can also cause wheezing.

Trauma and tumors are much rarer causes of wheezing in infants. Trauma of any type to the tracheobronchial tree can cause an obstruction to airflow. Accidental or nonaccidental aspirations, burns, or scalds of the tracheobronchial tree can cause inflammation of the airways and subsequent wheezing. Any space-occupying lesion, either in the lung itself or extrinsic to the lung, can cause tracheobronchial compression and obstruction to airflow.

CLINICAL MANIFESTATIONS

History and Physical Examination

The initial history of a wheezing infant should describe the recent event including onset, duration, and associated factors (Table 391-2). *Birth history* includes weeks of gestation, neonatal intensive care unit admission, history of intubation or oxygen requirement, maternal complications including infection with herpes simplex virus or HIV, and prenatal smoke exposure. Past medical history includes any comorbid conditions including syndromes or associations. *Family history* of cystic fibrosis, immunodeficiencies, asthma in a 1st-degree relative, or any other recurrent respiratory conditions in children should be obtained. *Social history* should include an environmental history including any smokers at home, inside or out, daycare exposure, number of siblings, occupation of inhabitants of the home, pets, tuberculosis exposure, and concerns regarding home environment (e.g., dust mites, construction dust, heating and cooling techniques, mold, cockroaches). The patient's growth chart should be reviewed for signs of failure to thrive.

On **physical examination,** evaluation of the patient's vital signs with special attention to the respiratory rate and the pulse oximetry reading for oxygen saturation is an important initial step. The **exam** is often dominated by wheezing. Auscultation might reveal fine crackles or overt wheezes, with prolongation of the expiratory phase of breathing.

Table 391-2	Pertinent Medical History in the Wheezing Infant
Did the onset of symptoms begin at birth or thereafter? Is the infant a noisy breather and when is it most prominent? Is the noisy breathing present on inspiration, expiration, or both? Is there a history of cough apart from wheezing? Was there an earlier lower respiratory tract infection? Is there a history of recurrent upper or lower respiratory tract infections? Have there been any emergency department visits, hospitalizations, or intensive care unit admissions for respiratory distress? Is there a history of eczema? Does the infant cough after crying or cough at night? How is the infant growing and developing? Is there associated failure to thrive? Is there a history of electrolyte abnormalities? Are there signs of intestinal malabsorption including frequent, greasy, or oily stools? Is there a maternal history of genital herpes simplex virus infection? What was the gestational age at delivery? Was the patient intubated as a neonate? Does the infant bottle-feed in the bed or the crib, especially in a propped position? Are there any feeding difficulties including choking, gagging, arching, or vomiting with feeds? Is there any new food exposure? Is there a toddler in the home or lapse in supervision in which foreign-body aspiration could have occurred? Change in caregivers or chance of nonaccidental trauma?	

Wheezing produces an expiratory whistling sound that can be polyphonic or monophonic. Expiratory time may be prolonged. Biphasic wheezing can occur if there is a central, large airway obstruction. The degree of tachypnea does not always correlate with the degree of hypoxemia or hypercarbia, so pulse oximetry and noninvasive determination of carbon dioxide is essential. Work of breathing may be markedly increased, with nasal flaring and retractions. *Complete obstruction to airflow can eliminate the turbulence that causes wheezing; thus the lack of audible wheezing is not reassuring if the infant shows other signs of respiratory distress.* Barely audible breath sounds suggest very severe disease with nearly complete bronchiolar obstruction.

Aeration should be noted and a trial of a bronchodilator may be warranted to evaluate for any change in wheezing after treatment. Listening to breath sounds over the neck helps differentiate upper airway from lower airway sounds. The absence or presence of stridor should be noted and appreciated on inspiration. Signs of respiratory distress include tachypnea, increased respiratory effort, nasal flaring, tracheal tugging, subcostal and intercostal retractions, and excessive use of accessory muscles. In the upper airway, signs of atopy, including boggy turbinates and posterior oropharynx cobblestoning, can be evaluated in older infants. It is also useful to evaluate the skin of the patient for eczema and any significant hemangiomas; midline lesions may be associated with an intrathoracic lesion. Digital clubbing should be noted (see Chapter 374). Hyperinflation of the lungs can permit palpation of the liver and spleen.

Acute bronchiolitis is usually preceded by exposure to an older contact with a minor respiratory syndrome within the previous week. The infant first develops a mild upper respiratory tract infection with sneezing and clear rhinorrhea. This may be accompanied by diminished appetite and fever of 38.5-39°C (101-102°F), although the temperature can range from subnormal to markedly elevated. Gradually, respiratory distress ensues, with paroxysmal wheezy cough, dyspnea, and irritability. The infant is often tachypneic, which can interfere with feeding. The child does not usually have other systemic complaints, such as diarrhea or vomiting. Apnea may be more prominent than wheezing early in the course of the disease, particularly with very young infants (<2 mo old) or former premature infants.

Diagnostic Evaluation

Initial evaluation depends on likely etiology; a baseline chest radiograph, including posteroanterior and lateral films, is warranted in many cases and for any infant in acute respiratory distress, **but not routinely indicated in children with uncomplicated bronchiolitis.** Infiltrates are most often found in wheezing infants who have a pulse oximetry reading <93%, grunting, decreased breath sounds, prolonged inspiratory to expiratory ratio, and crackles. Pulse oximetry is indicated as hypoxia is common in bronchiolitis and may signify diffuse involvement, air trapping, ventilation–perfusion mismatching, and atelectasis. The chest radiograph may also be useful for evaluating hyperinflation (common in bronchiolitis and viral pneumonia), atelectasis signs of chronic disease such as bronchiectasis, or a space-occupying lesion causing airway compression. A trial of bronchodilator may be diagnostic as well as therapeutic because these medications can reverse conditions such as asthma but will not affect a fixed obstruction. Bronchodilators potentially can worsen a case of wheezing caused by tracheal or bronchial malacia. A sweat test to evaluate for cystic fibrosis and evaluation of baseline immune status are reasonable in infants with recurrent wheezing, failure to thrive, or complicated courses. Further evaluation such as upper gastrointestinal contrast x-rays, chest CT, bronchoscopy, bronchoalveolar lavage, ciliary biopsy, infant pulmonary function testing, video swallow study, and pH probe can be considered 2nd-tier diagnostic procedures in complicated patients.

The diagnosis of **acute bronchiolitis** is clinical, particularly in a previously healthy infant presenting with a 1st-time wheezing episode during a community outbreak. Chest radiography can reveal hyperinflated lungs with patchy atelectasis but is not indicated in all patients with bronchiolitis. The white blood cell and differential counts are usually normal. Viral testing (polymerase chain reaction, rapid immunofluorescence, or viral culture) is helpful if the diagnosis is uncertain or for epidemiologic purposes but is not indicated in uncomplicated bronchiolitis. Because concurrent bacterial infection (sepsis, pneumonia, meningitis) is highly unlikely, confirmation of viral bronchiolitis may obviate the need for a sepsis evaluation in the febrile infant older than 28 days and assist with respiratory precautions and isolation if the patient requires hospitalization.

Treatment

Treatment of an infant with wheezing depends on the underlying etiology. Response to bronchodilators is unpredictable, regardless of cause, but suggests a component of bronchial hyperreactivity. It is appropriate to administer albuterol aerosol and objectively observe the response. For children younger than 3 yr of age, it is acceptable to continue to administer inhaled medications through a metered-dose inhaler with mask and spacer if a therapeutic benefit is demonstrated. Therapy should be continued in all patients with asthma exacerbations from a viral illness.

The use of ipratropium bromide in this population is controversial, but it appears to be somewhat effective as an adjunct therapy. It is also useful in infants with significant tracheal and bronchial malacia who may be made worse by β_2-agonists such as albuterol because of the subsequent decrease in smooth muscle tone.

A trial of inhaled steroids may be warranted in a patient who has responded to multiple courses of oral steroids and who has moderate to severe wheezing or a significant history of atopy including food allergy or eczema. Inhaled corticosteroids are appropriate for maintenance therapy in patients with known reactive airways but are controversial when used for episodic or acute illnesses. Intermittent, high-dose inhaled corticosteroids are not recommended for intermittent wheezing. Early use of inhaled corticosteroids has not been shown to prevent the progression of childhood wheezing or affect the natural history of asthma in children.

Oral steroids are generally reserved for atopic wheezing infants thought to have asthma that is refractory to other medications. Their use in 1st-time wheezing infants or in infants who do not warrant hospitalization is controversial.

Infants with **acute bronchiolitis** who are experiencing respiratory distress (hypoxia, inability to take oral feedings, apnea, extreme tachypnea) should be hospitalized; risk factors for severe disease include age <12 wk, preterm birth, or underlying comorbidity such as cardiovascular, pulmonary, neurologic, or immunologic disease. The mainstay of treatment is supportive. Hypoxemic children should receive cool humidified oxygen. Sedatives are to be avoided because they can depress respiratory drive. The infant is sometimes more comfortable if sitting with head and chest elevated at a 30-degree angle with neck extended. There is a small risk of aspiration of oral feedings in infants with bronchiolitis, owing to tachypnea and the increased work of breathing. If there is any risk for further respiratory decompensation potentially necessitating tracheal intubation, the infant should not be fed orally but be maintained with parenteral fluids. Frequent suctioning of nasal and oral secretions often provides relief of distress or cyanosis. Suctioning of secretions is an essential part of the treatment of bronchiolitis. Oxygen is definitely indicated in all infants with hypoxia. High-flow nasal cannula therapy can reduce the need for intubation in patients with impending respiratory failure.

A number of agents have been proposed as adjunctive therapies for bronchiolitis. Bronchodilators may produce short-term improvement in clinical features. This must be placed in context of potential adverse effects and the lack of any evidence indicating improvement in overall course of the disease. Systematic reviews and meta-analyses of randomized controlled trials have failed to show a benefit from bronchodilators in uncomplicated bronchiolitis. Corticosteroids, whether parenteral, oral, or inhaled, have been used for bronchiolitis despite conflicting and often negative studies. Corticosteroids are not recommended in previously healthy infants with RSV. Ribavirin, an antiviral agent administered by aerosol, has been used for infants with RSV who have congenital heart disease or chronic lung disease. There is no convincing evidence of a positive impact on clinically important

outcomes such as mortality and duration of hospitalization. Antibiotics have no value unless there is coexisting bacterial infection. Likewise, there is no support for RSV immunoglobulin administration during acute episodes of RSV bronchiolitis in previously healthy children. Combined therapy with nebulized epinephrine and dexamethasone has been used with some success, but additional studies are needed to confirm its efficacy and investigate the long-term adverse effects in infants before this combination can be recommended. Nebulized hypertonic saline has been reported to have some benefit, and may shorten hospital length of stay. One study suggested that on demand therapy with inhaled epinephrine or saline was more effective than scheduled fixed dosing. Heliox delivered by tight fitting mask or by continuous positive airway pressure has been of some benefit in moderately to severely affected patients with bronchiolitis.

Certain (10%) low risk patients with bronchiolitis and an oxygen requirement may be discharged from the emergency department to receive **home oxygen therapy**. Criteria for home oxygen therapy includes: typical clinical features (no apnea, wheezing ± crackles); 2 mo-2 yr of age (>44 wk gestational age); first episode of wheezing; illness during RSV season; secretions managed by parents with bulb suctioning; smoke free home; reliable family with good access to healthcare; altitude ≤6,000 feet; absence of toxic appearance or proven bacterial disease; apparent life-threatening event; cardiac, pulmonary, immunodeficiency, or neuromuscular disorders; baseline oxygen requirement prior to current illness; mild illness as evident by feeding well and alert and active; minimal retractions; respiratory rate <50 breaths/min; oxygenation >90% on ≤0.5 L/min of oxygen. All patients must have follow-up within 24 hr of discharge from the emergency room by their primary care provider or by the emergency room staff. Chest physiotherapy does not improve disease course in hospitalized infants with bronchiolitis who are not mechanically ventilated.

PROGNOSIS

Infants with **acute bronchiolitis** are at highest risk for further respiratory compromise in the 1st 48-72 hr after onset of cough and dyspnea; the child may be desperately ill with air hunger, apnea, and respiratory acidosis. The case fatality rate is <1%, with death attributable to apnea, respiratory arrest, or severe dehydration. After this critical period, symptoms can persist. The median duration of symptoms in ambulatory patients is approximately 14 days; 10% may be symptomatic at 3 wk. There is a higher incidence of wheezing and asthma in children with a history of bronchiolitis unexplained by family history or other atopic syndromes. It is unclear whether bronchiolitis incites an immune response that manifests as asthma later or whether those infants have an inherent predilection for asthma that is merely unmasked by their episode of viral bronchiolitis.

PREVENTION

Reduction in the severity and incidence of **acute bronchiolitis** because of RSV is possible through the administration of pooled hyperimmune RSV intravenous immunoglobulin and palivizumab, an intramuscular monoclonal antibody to the RSV F protein, before and during RSV season. Palivizumab should be considered for infants younger than 2 yr of age with chronic lung disease, a history of prematurity, and some forms of congenital heart disease (see Chapter 260). Meticulous hand hygiene is the best measure to prevent nosocomial transmission.

Bibliography is available at Expert Consult.

391.2 Bronchitis

Lauren E. Camarda and Denise M. Goodman

Nonspecific bronchial inflammation is termed **bronchitis** and occurs in multiple childhood conditions. **Acute bronchitis** is a syndrome, usually viral in origin, with cough as a prominent feature.

Acute tracheobronchitis is a term used when the trachea is prominently involved. Nasopharyngitis may also be present, and a variety of viral and bacterial agents, such as those causing influenza, pertussis, and diphtheria, may be responsible. Isolation of common bacteria such as *Staphylococcus aureus* and *Streptococcus pneumoniae* from the sputum might not imply a bacterial cause that requires antibiotic therapy.

ACUTE BRONCHITIS

Clinical Manifestations

Acute bronchitis often follows a viral upper respiratory tract infection. It is more common in the winter when respiratory viral syndromes predominate. The tracheobronchial epithelium is invaded by the infectious agent, leading to activation of inflammatory cells and release of cytokines. Constitutional symptoms including fever and malaise follow. The tracheobronchial epithelium can become significantly damaged or hypersensitized, leading to a protracted cough lasting 1-3 wk.

The child first presents with nonspecific upper respiratory infectious symptoms, such as rhinitis. Three to 4 days later, a frequent, dry, hacking cough develops, which may or may not be productive. After several days, the sputum can become purulent, indicating leukocyte migration but not necessarily bacterial infection. Many children swallow their sputum which can produce emesis. Chest pain may be a prominent complaint in older children and is exacerbated by coughing. The mucus gradually thins, usually within 5-10 days, and then the cough gradually abates. The entire episode usually lasts about 2 wk and seldom longer than 3 wk.

Findings on physical examination vary with the age of the patient and stage of the disease. Early findings are absent or include low-grade fever and upper respiratory signs such as nasopharyngitis, conjunctivitis, and rhinitis. Auscultation of the chest may be unremarkable at this early phase. As the syndrome progresses and cough worsens, breath sounds become coarse, with coarse and fine crackles and scattered high-pitched wheezing. Chest radiographs are normal or can have increased bronchial markings.

The principal objective of the clinician is to exclude pneumonia, which is more likely caused by bacterial agents requiring antibiotic therapy. Absence of abnormality of vital signs (tachycardia, tachypnea, fever) and a normal physical examination of the chest reduce the likelihood of pneumonia.

Differential Diagnosis

Persistent or recurrent symptoms should lead the clinician to consider entities other than acute bronchitis. Many entities manifest with cough as a prominent symptom (Table 391-3).

Treatment

There is no specific therapy for acute bronchitis. The disease is self-limited, and antibiotics, although often prescribed, do not hasten improvement. Frequent shifts in position can facilitate pulmonary drainage in infants. Older children are sometimes more comfortable with humidity, but this does not shorten the disease course. Cough suppressants can relieve symptoms but can also increase the risk of suppuration and inspissated secretions and, therefore, should be used judiciously. Antihistamines dry secretions and are not helpful; expectorants are likewise not indicated. Nonprescription cough and cold medicines should not be used in children younger than 2 yr of age and their use is cautioned in children age 2-11 yr.

CHRONIC BRONCHITIS

Chronic bronchitis is well recognized in adults, formally defined as 3 mo or longer of productive cough each year for 2 or more yr. The disease can develop insidiously, with episodes of acute obstruction alternating with quiescent periods. A number of predisposing conditions can lead to progression of airflow obstruction or chronic obstructive pulmonary disease, with smoking as the major factor (up to 80% of patients have a smoking history). Other conditions include air pollution, occupational exposures, and repeated infections. In children, cystic fibrosis, bronchopulmonary dysplasia, and bronchiectasis must be ruled out.

The applicability of this definition to children is unclear. The existence of chronic bronchitis as a distinct entity in children is

Acquired	Foreign-body aspiration, tracheal or esophageal

controversial. Like adults, children with chronic inflammatory diseases or those with toxic exposures can develop damaged pulmonary epithelium. Thus, chronic or recurring cough in children should lead the clinician to search for underlying pulmonary or systemic disorders (see Table 391-3). One proposed entity that shares characteristics with asthma and other forms of suppurative lung disease is persistent or protracted bacterial bronchitis. Protracted bacterial bronchitis is defined as a chronic (>3 wk) wet cough, characterized by bacterial counts of 10^4 colony-forming units/mL or greater from bronchoalveolar lavage and resolution of cough within 2 wk of treatment with antimicrobial therapy.

CIGARETTE SMOKING AND AIR POLLUTION

Exposure to environmental irritants, such as tobacco smoke and air pollution, can incite or aggravate cough. There is a well-established association between tobacco exposure and pulmonary disease, including bronchitis and wheezing. This can occur through cigarette smoking or by exposure to passive smoke. Marijuana smoke and inhalants are other irritants sometimes overlooked when eliciting a history.

A number of pollutants compromise lung development and likely precipitate lung disease, including particulate matter, ozone, acid vapor, and nitrogen dioxide. Proximity to motor vehicle traffic is an important source of these pollutants. Because these substances coexist in the atmosphere, the relative contribution of any 1 to pulmonary symptoms is difficult to discern.

391.3 Plastic Bronchitis

Brett J. Bordini

Plastic bronchitis is a rare condition characterized by recurrent episodes of airway obstruction secondary to the formation of large proteinaceous branching casts that take on the shape of and obstruct the tracheobronchial tree. It is not a single disease entity, but rather represents an altered state of respiratory epithelial function and is most frequently encountered in the setting of underlying pulmonary or congenital cardiac disease, although there have been reports of plastic bronchitis complicating lymphangitic disorders, pulmonary infections, and the acute chest syndrome of sickle cell disease. In comparison to the smaller bronchial and bronchiolar casts seen with mucus plugging, the lesions of plastic bronchitis are more extensive, with casts that can outline large segments of the airway to the level of the terminal bronchioles (Fig. 391-1). These casts may be spontaneously expectorated or may require bronchoscopic removal for relief of potentially fatal airway obstruction. Cast composition varies, though typically consists of either a fibrin-predominant or mucin-predominant laminated matrix with or without inflammatory cell infiltration. Plastic bronchitis may be classified according to an associated disease, the cast histology, or a combination.

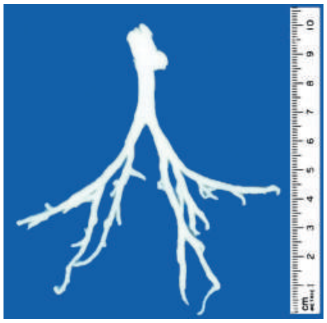

Figure 391-1 Tracheobronchial casts following bronchoscopic extraction. Casts show branched architecture corresponding to the bronchial tree. *(From Hasan RA, Black C, Reddy R: Plastic bronchitis in children.* Fetal Pediatr Pathol *31;87–93, 2012, Fig. 5, p. 91.)*

EPIDEMIOLOGY

Plastic bronchitis is rare, and its true prevalence in the pediatric population is not known but is estimated to be 6.8 cases per 100,000 patients. Prevalence does vary in relation to the underlying associated disease state, with rates as high as 14% estimated in patients who have undergone staged palliation of complex cyanotic congenital heart disease, and much lower rates seen complicating asthma and atopic disease. A slight male predominance exists for cast formation in the setting of structural heart disease, whereas cast formation in the setting of asthma and atopic disease demonstrates a female predominance.

PATHOGENESIS

The mechanism of cast formation is unclear, although it is believed to vary based on the underlying disease association and cast type. One classification system differentiates type 1 inflammatory casts, composed of primarily of fibrin with neutrophilic and more often eosinophilic infiltration, and type 2 casts, composed primarily of mucin with little to no cellular infiltration. Type 1 casts may be associated with inflammatory and infectious disorders of the lung, while type 2 casts may be associated with structural heart disease. However, these distinctions are not absolute; patients with structural heart disease can have mucin-predominant casts and patients with asthma or atopic disease can have fibrin-predominant casts, with both mucin casts and fibrin casts demonstrating various degrees of cellular infiltration.

Cast formation in the setting of structural heart disease may result from alterations in pulmonary blood flow or from alterations in lymphatic drainage, either congenital or secondary to the protein-losing enteropathy associated with Fontan physiology. Mucin-predominant casts are believed to arise secondary to mucus gland hypersecretion as well as decreased mucociliary clearance.

CLINICAL MANIFESTATIONS

Patients with plastic bronchitis may present with cough, dyspnea, wheeze, or pleuritic chest pain. Depending on the degree of airway obstruction, patients may be hypoxemic or in severe respiratory distress. The expectoration of large, branched casts that are often tan in

color and rubbery in consistency is pathognomonic for plastic bronchitis. Lung examination may reveal diminished breath sounds or wheezing in the affected area. Rarely, auscultation may reveal a sound similar to a flag flapping in the wind *(bruit de drapeau)*, believed to be related to the free end of a cast striking the bronchial wall during inspiration or expiration. Further examination may provide clues to underlying comorbidities.

DIAGNOSIS

The expectoration or endoscopic discovery of large tracheobronchial casts is pathognomonic for plastic bronchitis. History should be directed at assessing for conditions known to be have an associated risk of tracheobronchial cast formation, such as uncorrected or surgically palliated complex congenital heart disease; a history of atopic disease or asthma; lymphangitic disorders such as Noonan syndrome, Turner syndrome, lymphangiectasia, and yellow nail syndrome; sickle cell disease; and infectious exposures, particularly exposure to tuberculosis or atypical mycobacteria. Other predisposing conditions include cystic fibrosis, allergic bronchopulmonary aspergillosis, bronchiectasis, toxic inhalants, and granulomatous lung diseases.

Physical examination may provide indications of an underlying diagnosis. Digital clubbing of the fingers or toes may suggest long-standing hypoxemia associated with cardiac or pulmonary disease. Cardiac examination may provide information suggesting the presence of unrecognized structural heart disease.

Chest radiography may demonstrate collapse of the involved areas of the lung, or areas of bronchiectasis distal to sites of long-standing obstruction.

There should be a high index of suspicion for plastic bronchitis in patients with known comorbidities who present with sudden respiratory decompensation. In the absence of cast expectoration, direct visualization of casts via bronchoscopy is required for diagnosis and is potentially therapeutic in relieving airway obstruction. Cast histology should be defined so as to allow for specific therapies directed at preventing recurrence. In particular, the predominant component of the cast's laminated matrix—either fibrin or mucin—should be defined, and signs of inflammation or infiltration, such as the presence of neutrophils, eosinophils, or Charcot-Leyden crystals, should be documented.

TREATMENT

Treatment is directed at correcting the underlying condition associated with the development of plastic bronchitis, at relieving acute airway obstruction secondary to the presence of casts, and at preventing the development of further casts. Rigid or flexible bronchoscopy is typically required for cast removal. If the predominant content of the cast is known, therapy with either mucolytics or fibrinolytics may be considered as an adjunct to direct removal, and aerosolized fibrinolytics such as tissue plasminogen activator or mucolytics such as *N*-acetylcysteine or deoxyribonuclease may be used for prevention of recurrence. Bronchodilators should be used appropriately in the setting of reactive airway disease, and inhaled or systemic corticosteroids, low-dose azithromycin, and leukotriene inhibitors may be used to minimize airway inflammation. MRI lymphangiography may identify abnormal lymphatic vessels that may benefit from lymphatic embolization procedures.

COMPLICATIONS AND PROGNOSIS

Prognosis is related primarily to the underlying condition associated with the development of plastic bronchitis. Patients whose plastic bronchitis is related to surgically palliated complex congenital heart disease are at high risk for plastic bronchitis-related mortality. Mortality can be high if casts obstruct significant portions of the airway, regardless of underlying etiology. Mortality estimates vary from 6-50% in the setting of asthma or atopic disease, and from 28-60% in the setting of complex congenital heart disease, with central airway obstruction leading to death in the majority of patients.

Chapter 392

Emphysema and Overinflation

Steven R. Boas and Glenna B. Winnie

Pulmonary emphysema consists of distention of air spaces with irreversible disruption of the alveolar septa. It can involve part or all of a lung. **Overinflation** is distention with or without alveolar rupture and is often reversible. **Compensatory overinflation** can be acute or chronic and occurs in normally functioning pulmonary tissue when, for any reason, a sizable portion of the lung is removed or becomes partially or completely airless, which can occur with pneumonia, atelectasis, empyema, and pneumothorax. **Obstructive overinflation** results from partial obstruction of a bronchus or bronchiole, when it becomes more difficult for air to leave the alveoli than to enter. Air gradually accumulates distal to the obstruction, the so-called bypass, ball-valve, or check-valve type of obstruction.

LOCALIZED OBSTRUCTIVE OVERINFLATION

When a ball-valve type of obstruction partially occludes the main stem bronchus, the entire lung becomes overinflated; individual lobes are affected when the obstruction is in lobar bronchi. Segments or subsegments are affected when their individual bronchi are blocked. When most or all of a lobe is involved, the percussion note is hyperresonant over the area, and the breath sounds are decreased in intensity. The distended lung can extend across the mediastinum into the opposite hemithorax. Under fluoroscopic scrutiny during exhalation, the overinflated area does not decrease, and the heart and the mediastinum shift to the opposite side because the unobstructed lung empties normally.

Unilateral Hyperlucent Lung

The differential diagnosis for of this resultant **unilateral hyperlucent lung** is quite broad and can involve the lung parenchyma, airways, pulmonary vasculature, chest wall (see Chapter 417), and mediastinum. Localized obstructions that can be responsible for overinflation include airway foreign bodies and the inflammatory reaction to them (see Chapter 387), abnormally thick mucus (cystic fibrosis, Chapter 403), endobronchial tuberculosis or tuberculosis of the tracheobronchial lymph nodes (see Chapter 215), and endobronchial or mediastinal tumors.

Patients with unilateral hyperlucent lung can present with **clinical manifestations** of pneumonia, but in some patients the condition is discovered only when a chest radiograph is obtained for an unrelated reason. A few patients have hemoptysis. Physical findings can include hyperresonance and a small lung with the mediastinum shifted toward the more abnormal lung.

Swyer-James or Macleod Syndrome

The condition is thought to result from an insult to the lower respiratory tract following most commonly adenovirus (see Chapter 262), or respiratory syncytial virus (see Chapter 260), *Mycoplasma pneumoniae* (see Chapter 223), or measles (see Chapter 246). Clinically, children with this condition often have chronic cough, recurrent pneumonia, and wheezing, although some are asymptomatic. Some patients show a classic mediastinal shift away from the lesion with exhalation. CT scanning or bronchography can often demonstrate bronchiectasis. Ventilation–perfusion scans can be helpful in the diagnosis. In some patients, previous chest radiographs have been normal or have shown only an acute pneumonia, suggesting that a hyperlucent lung is an acquired lesion. No specific treatment is known; it may become less symptomatic with time. Indications as to which children would benefit from surgery remain controversial.

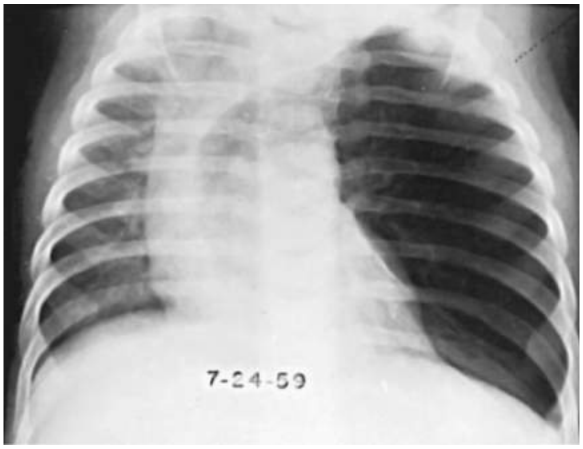

Figure 392-1 Congenital left upper lobe emphysema. Note the extension of the emphysematous lobe into the left lower lobe and its displacement of the mediastinum toward the right.

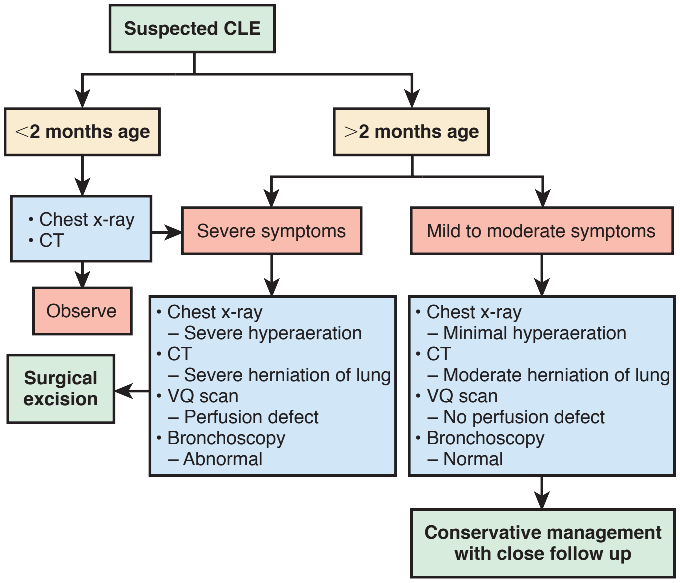

Figure 392-2 Algorithm for evaluation and treatment of congenital lobar emphysema (CLE). *(Adapted from Karnak I, Senocak ME, Ciftci AO, et al: Congenital lobar emphysema: diagnostic and therapeutic considerations,* J Pediatr Surg *34:1347–1351, 1999, Fig. 4.)*

Congenital Lobar Emphysema

Congenital lobar emphysema (CLE) can result in severe respiratory distress in early infancy and can be caused by localized obstruction. Familial occurrence has been reported. In 50% of cases, a cause of CLE can be identified. Congenital deficiency of the bronchial cartilage, external compression by aberrant vessels, bronchial stenosis, redundant bronchial mucosal flaps, and kinking of the bronchus caused by herniation into the mediastinum have been described as leading to bronchial obstruction and subsequent CLE and commonly affects the left upper lobe.

Clinical manifestations usually become apparent in the neonatal period but are delayed for as long as 5-6 mo in 5% of patients. Many cases are diagnosed by antenatal ultrasonography. Babies with prenatally diagnosed cases are not always symptomatic at birth. In some patients, CLE remains undiagnosed until school age or beyond. Clinical signs range from mild tachypnea and wheeze to severe dyspnea with cyanosis. CLE can affect 1 or more lobes; it affects the upper and middle lobes, and the left upper lobe is the most common site. The affected lobe is essentially nonfunctional because of the overdistention, and atelectasis of the ipsilateral normal lung can ensue. With further distention, the mediastinum is shifted to the contralateral side, with impaired function seen as well (Fig. 392-1). A radiolucent lobe and a mediastinal shift are often revealed by radiographic examination. A CT scan can demonstrate the aberrant anatomy of the lesion, and MRI or MR angiography can demonstrate any vascular lesions, which might be causing extraluminal compression. Nuclear imaging studies are useful to demonstrate perfusion defects in the affected lobe. Figure 392-2 outlines evaluation of an infant presenting with suspected CLE. The differential diagnosis includes pneumonia with or without an effusion, pneumothorax, and cystic adenomatoid malformation.

Treatment by immediate surgery and excision of the lobe may be lifesaving when cyanosis and severe respiratory distress are present, but some patients respond to medical treatment. Selective intubation of the unaffected lung may be of value. Some children with apparent CLE have reversible overinflation, without the classic alveolar septal rupture implied in the term *emphysema.* Bronchoscopy can reveal an endobronchial lesion.

Pulmonary Vascular Abnormalities

Unilateral hyperlucency may result from **unilateral pulmonary agenesis** (see Chapter 395) that typically presents in the neonatal period. Volume loss of the affected lung results in a mediastinal shift with hyperinflation of the contralateral lung. An **anomalous origin of the left pulmonary artery** (see Chapter 432), also known as a pulmonary artery sling, can impinge the right mainstem bronchus with resultant right-sided hyperinflation or atelectasis producing hyperlucency on either the ipsilateral or contralateral side. **Pulmonary venolobar syndrome** (see Chapter 426), also known as scimitar syndrome, can also result in a hyperlucent contralateral lung dependent on the extent of hypoplasia of the right lung.

GENERALIZED OBSTRUCTIVE OVERINFLATION

Acute generalized overinflation of the lung results from widespread involvement of the bronchioles and is usually reversible. It occurs more commonly in infants than in children and may be secondary to a number of clinical conditions, including asthma, cystic fibrosis, acute bronchiolitis, interstitial pneumonitis, atypical forms of acute laryngotracheobronchitis, aspiration of zinc stearate powder, chronic passive congestion secondary to a congenital cardiac lesion, and miliary tuberculosis.

Pathology

In chronic overinflation, many of the alveoli are ruptured and communicate with one another, producing distended saccules. Air can also enter the interstitial tissue (i.e., interstitial emphysema), resulting in pneumomediastinum and pneumothorax (see Chapters 412 and 411).

Clinical Manifestations

Generalized obstructive overinflation is characterized by dyspnea, with difficulty in exhaling. The lungs become increasingly overdistended, and the chest remains expanded during exhalation. An increased respiratory rate and decreased respiratory excursion result from the overdistention of the alveoli and their inability to be emptied normally through the narrowed bronchioles. Air hunger is responsible for forced respiratory movements. Overaction of the accessory muscles of respiration results in retractions at the suprasternal notch, the supraclavicular spaces, the lower margin of the thorax, and the intercostal spaces. Unlike the flattened chest during inspiration and exhalation in cases of laryngeal obstruction, minimal reduction in the size of the overdistended chest during exhalation is observed. The percussion note is hyperresonant. On auscultation, the inspiratory phase is usually less prominent than the expiratory phase, which is prolonged and roughened. Fine or medium crackles may be heard. Cyanosis is more common in the severe cases.

Figure 392-3 Increased transradiancy in the right lower zone. A large emphysematous bulla occupies the lower half of the right lung, and the apical changes are in keeping with previous tuberculosis. *(From Padley SPG, Hansell DM: Imaging techniques. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, 2008, Mosby, Fig. 1-48.)*

Diagnosis

Radiographic and fluoroscopic examinations of the chest assist in establishing the diagnosis. Both leaves of the diaphragm are low and flattened, the ribs are farther apart than usual, and the lung fields are less dense. The movement of the diaphragm during exhalation is decreased, and the excursion of the low, flattened diaphragm in severe cases is barely discernible. The anteroposterior diameter of the chest is increased, and the sternum may be bowed outward.

Bullous Emphysema

Bullous emphysematous blebs or cysts (pneumatoceles) result from overdistention and rupture of alveoli during birth or shortly thereafter, or they may be sequelae of pneumonia and other infections. They have been observed in tuberculosis lesions during specific antibacterial therapy. These emphysematous areas presumably result from rupture of distended alveoli, forming a single or multiloculated cavity. The cysts can become large and might contain some fluid; an air–fluid level may be demonstrated on the radiograph (Fig. 392-3). The cysts should be differentiated from pulmonary abscesses. In most cases, the cysts disappear spontaneously within a few months, although they can persist for a year or more. Aspiration or surgery is not indicated except in cases of severe respiratory and cardiac compromise.

Subcutaneous Emphysema

Subcutaneous emphysema results from any process that allows free air to enter into the subcutaneous tissue (Fig. 392-4). The most common causes include pneumomediastinum or pneumothorax. Additionally, it can be a complication of fracture of the orbit, which permits free air to escape from the nasal sinuses. In the neck and thorax, subcutaneous emphysema can follow tracheotomy, deep ulceration in the pharyngeal region, esophageal wounds, or any perforating lesion of the larynx or trachea. It is occasionally a complication of thoracentesis, asthma, or abdominal surgery. Rarely, air is formed in the subcutaneous tissues by gas-producing bacteria.

Tenderness over the site of emphysema and a crepitant quality on palpation of the skin are classic manifestations. Subcutaneous emphysema is usually a self-limited process and requires no specific treatment. Minimization of activities that can increase airway pressure (cough, performance of high-pressure pulmonary function testing maneuvers) is recommended. Resolution occurs by resorption of subcutaneous air after elimination of its source. Rarely, dangerous compression of the trachea by air in the surrounding soft tissue requires surgical intervention.

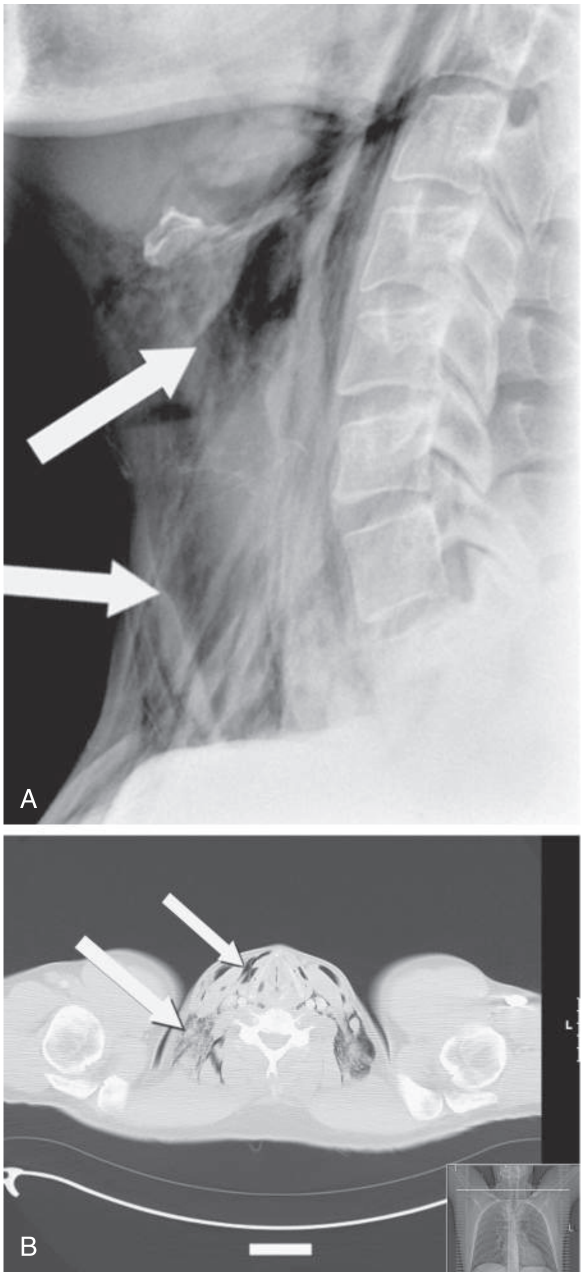

Figure 392-4 **A,** Lateral X-ray of neck showing subcutaneous emphysema. **B,** Axial section CT neck/thorax showing subcutaneous emphysema and pneumomediastinum. *(From Zakaria R, Khwaja H. Subcutaneous emphysema in a case of infective sinusitis: a case report.* J Med Case Rep *4:235, 2010, Figs, 1 and 2.)*

Chapter 393

α_1-Antitrypsin Deficiency and Emphysema

Glenna B. Winnie and Steven R. Boas

Although it rarely causes lung disease in children, homozygous deficiency of α_1-antitrypsin (α_1-AT) is an important cause of early-onset severe panacinar pulmonary emphysema in adults in the 3rd and 4th decades of life and an important cause of liver disease in children (see Chapter 357.5). It is associated with panniculitis and vasculitis in adults.

PATHOGENESIS

The type and concentration of α_1-AT are inherited as a series of codominant alleles on chromosomal segment 14q31-32.3. (See Chapter 357.5 for a discussion of genotypes and liver disease.) The autosomal recessive deficiency affects 1 in 1,600-2,500 people, or approximately 575,000 (estimated number of deficiency allele combinations) people in the United States, but is underdiagnosed. The highest risk for α_1-AT deficiency is found in whites, followed by Hispanics and Blacks, with the lowest prevalence among Mexican Americans, and little to no risk for Asians. Worldwide there are an estimated 116,000,000 carriers and 1,100,000 subjects with severe α_1-AT deficiency. The normal α_1-AT PiM protein is secreted by the liver into the circulation at a rate of approximately 34 mg/kg/day; it is also produced by lung epithelial cells and monocytes. Mutant protein is not produced (null) or is misfolded (PiZ and others); it can polymerize in the endoplasmic reticulum or be degraded, with subsequent low serum levels. Early adult-onset emphysema associated with α_1-AT deficiency occurs most commonly with PiZZ (mutation in *SERPINA1* gene), although Pi (null) (null) and, to a lesser extent, other mutant Pi types such as SZ have been associated with emphysema.

α_1-AT and other serum antiproteases help inactivate proteolytic enzymes released from dead bacteria or leukocytes in the lung. Deficiency of these antiproteases leads to an accumulation of proteolytic enzymes in the lung, resulting in destruction of pulmonary tissue with subsequent development of emphysema. Furthermore, polymerized mutant protein in the lungs may be proinflammatory. The concentration of proteases (elastase) in the patients' leukocytes may also be an important factor in determining the severity of clinical pulmonary disease with a given level of α_1-AT.

CLINICAL MANIFESTATIONS

Most patients who have the PiZZ defect have little or no detectable pulmonary disease during childhood. A few have early onset of chronic pulmonary symptoms, including dyspnea, wheezing, and cough, and panacinar emphysema has been documented by lung biopsy; it is probable that these findings occur secondarily to infection, causing inflammation with consequent early disease. Smoking greatly increases the risk of emphysema in patients with mutant Pi types. Although newborn screening to identify children with PiZZ phenotype does not affect parental smoking habits, it does decrease smoking rates among affected adolescents.

Physical examination in childhood is usually normal. It very rarely reveals growth failure, an increased anteroposterior diameter of the chest with a hyperresonant percussion note, crackles if there is active infection, and clubbing. Severe emphysema can depress the diaphragm, making the liver and spleen more easily palpable.

LABORATORY FINDINGS

Serum immunoassay measures low levels of α_1-AT; normal serum levels are 150-350 mg/dL. Serum electrophoresis reveals the phenotype, and genotype is determined by polymerase chain reaction. In the rare patient with lung disease in adolescence, chest radiograph reveals overinflation with depressed diaphragms. Chest CT can show more hyperexpansion in the lower lung zones, with occasional bronchiectasis; CT densitometry can be a sensitive method to follow changes in lung disease. Lung function testing is usually normal in children, but it can show airflow obstruction and increased lung volumes, particularly in adolescents who smoke.

TREATMENT

Therapy for α_1-AT deficiency is intravenous replacement with enzyme derived from pooled human plasma. A level of 80 mg/dL is protective for emphysema. This target level for augmentation therapy is usually achieved with doses of 60 mg/kg IV weekly and results in the appearance of the transfused antiprotease in pulmonary lavage fluid. The Food and Drug Administration has approved the use of purified blood-derived human enzyme for ZZ and null-null patients. Replacement therapy appears most beneficial for those with moderately severe obstructive lung disease (forced expiratory volume in 1 sec is 30-65% of predicted) or those with mild lung disease experiencing a rapid decline in lung function. Augmentation therapy is not indicated for persons with the PiMZ type who have pulmonary disease, because their disease is not from enzyme deficiency. Recombinant sources of α_1-AT are under development, but current products are rapidly cleared from the circulation when given intravenously; they may be useful for inhalation therapy. Inhalation of the plasma-derived product is under evaluation. Lung transplantation has been performed for end-stage disease.

SUPPORTIVE THERAPY

Standard supportive therapy for chronic lung disease includes aggressive treatment of pulmonary infection, routine use of pneumococcal and influenza vaccines, bronchodilators, and advice about the serious risks of smoking. Such treatment is also indicated for asymptomatic family members found to have PiZZ or null-null phenotypes, but not those with PiMZ type. The clinical significance of the PiSZ type is unclear, but nonspecific treatment is reasonable. All persons with low levels of serum antiprotease should be warned that the development of emphysema is partially mediated by environmental factors and that cigarette smoking is particularly deleterious. Although identification of affected persons could help prevent development of obstructive lung disease, population screening programs are currently suspended; however, there is increased emphasis on targeted screening programs.

Chapter 394
Other Distal Airway Diseases

394.1 Bronchiolitis Obliterans

Steven R. Boas

EPIDEMIOLOGY

Bronchiolitis obliterans (BO), a chronic obstructive lung disease of the bronchioles and smaller airways, results from an insult to the lower respiratory tract leading to fibrosis of the small airways. In the nontransplant patient, BO most commonly occurs in the pediatric population after respiratory infections, particularly adenovirus (see Chapter 262), but also *Mycoplasma pneumoniae* (see Chapter 223), measles (see Chapter 246), *Legionella pneumophila* (see Chapter 208), influenza (see Chapter 258), and pertussis (see Chapter 197); other causes

Table 394-1 Etiology of Bronchiolitis Obliterans
POSTINFECTION Adenovirus types 3, 7, and 21 Influenza Parainfluenza Measles Respiratory syncytial virus Varicella *Mycoplasma pneumoniae*
POSTTRANSPLANTATION Chronic rejection of lung or heart/lung transplantation Graft-versus-host disease associated with bone marrow transplantation
CONNECTIVE TISSUE DISEASE Juvenile idiopathic arthritis Sjögren syndrome Systemic lupus erythematosus
TOXIC FUME INHALATION NO_2 NH_3 Diacetyl flavorings (microwave popcorn)
CHRONIC HYPERSENSITIVITY PNEUMONITIS Avian antigens Mold
ASPIRATION Stomach contents: gastroesophageal reflux Foreign bodies
DRUGS Penicillamine Cocaine
STEVENS-JOHNSON SYNDROME Idiopathic Drug induced Infection related

From Moonnumakal SP, Fan LL: Bronchiolitis obliterans in children, Curr Opin Pediatr *20:272–278, 2008.*

include inflammatory diseases (juvenile idiopathic arthritis, systemic lupus erythematosus [see Chapter 158], scleroderma [see Chapter 160], Stevens-Johnson syndrome [see Chapter 152]), and inhalation of toxic fumes or particulate exposure (NO_2, incinerator fly ash, NH_3, diacetyl flavorings from microwave popcorn, papaverine, fiberglass) (Table 394-1).

Bronchiolitis obliterans syndrome (BOS), a clinical entity that relates to graft deterioration after transplantation as a result of progressive airway, is recognized as a long-term complication of lung and bone marrow transplantation; more than one-third of survivors of lung transplantation can develop this disorder. BOS occurs in all age groups, and the prevalence in 1 pediatric autopsy series was 2 per 1,000. The incidence of new cases appears to be decreasing. BOS appears to be more common among older children and adolescents than infants and toddlers. There is some evidence that postinfection obliterans may be more common in the southern hemisphere and among persons of Asian descent.

PATHOGENESIS

After the initial insult, inflammation affecting terminal bronchioles, respiratory bronchioles, and alveolar ducts can result in the obliteration of the airway lumen (Fig. 394-1). Epithelial damage resulting in abnormal repair is characteristic of BO. Complete or partial obstruction of the airway lumen can result in air trapping or atelectasis. **Bronchiolitis obliterans organizing pneumonia (BOOP)** is a fibrosing lung disease that includes the histologic features of BO with extension of the inflammatory process from distal alveolar ducts into alveoli and proliferation of fibroblasts. BOS appears histologically similar to BO.

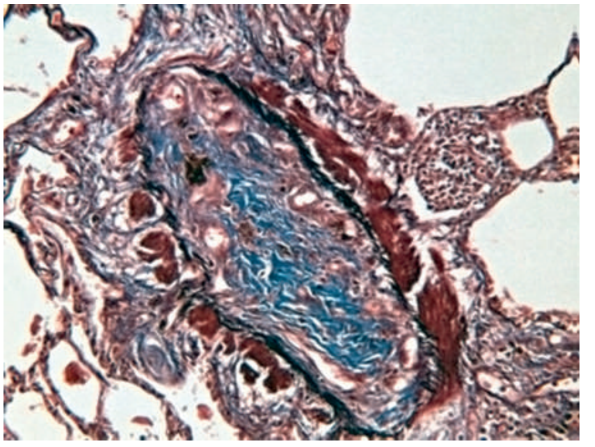

Figure 394-1 Complete obliteration of airway lumen with fibromyxoid tissue in lung transplant recipient with bronchiolitis obliterans. *(From Kurland G, Michelson P: Bronchiolitis obliterans in children,* Pediatr Pulmonol *39:193–208, 2005.)*

The etiology of BOS is unclear, however, and may be unrelated to the mechanisms responsible for BO in nontransplant patients.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Cough, fever, cyanosis, dyspnea, chest pain, and respiratory distress followed by initial improvement may be the initial signs of BO. In this phase, BO is easily confused with pneumonia, bronchitis, or bronchiolitis. Progression of the disease can ensue, with increasing dyspnea, chronic cough, sputum production, and wheezing. Physical examination findings are usually nonspecific and can include wheezing, hypoxemia, and crackles. Chest radiographs may be relatively normal compared with the extent of physical findings but can demonstrate hyperlucency and patchy infiltrates. Occasionally, a Swyer-James syndrome (unilateral hyperlucent lung; see Chapter 392) develops. Pulmonary function tests demonstrate variable findings but typically show signs of airway obstruction with a variable degree of bronchodilator response. Exercise testing shows reduced exercise capacity and impaired oxygen consumption. Ventilation–perfusion scans reveal a typical moth-eaten appearance of multiple matched defects in ventilation and perfusion. High-resolution chest CT often demonstrates patchy areas or a mosaic pattern of hyperlucency, air trapping, and bronchiectasis (Fig. 394-2). (Table 394-2 provides an overview of CT findings of BO and related disorders.) Physical and radiologic signs can wax and wane over weeks or months. Open lung biopsy or transbronchial biopsy remains the best means of establishing the diagnosis of BO or BOOP.

TREATMENT

No definitive therapy exists for BO. Administration of corticosteroids may be beneficial. Immunomodulatory agents, such as sirolimus, tacrolimus, aerosolized cyclosporine, hydroxychloroquine, and macrolide antibiotics, have been used in post–lung transplantation recipients with BO with variable success. Supportive measures with oxygen, antibiotics for secondary infections, and bronchodilators are adjunct therapies. The role of gastroesophageal reflux and its association with BO has been raised, with treatment suggested whenever the diagnosis is made. Azithromycin may be effective in patients with BOS. For BOOP, use of oral corticosteroids for up to 1 yr has been advocated as first-line therapy for symptomatic and progressive disease. Patients with asymptomatic or nonprogressive BOOP can be observed.

PROGNOSIS

Some patients with BO experience rapid deterioration in their condition and die within weeks of the initial symptoms; most nontransplant patients survive with chronic disability. BOS has a higher mortality

rate. Unlike in BO, total recovery is seen in 60-80% of patients with BOOP, although this depends on the underlying systemic disease. BOOP can relapse, especially if treatment duration is <1 yr; BOOP is amenable to repeat courses of oral corticosteroids. Unlike the more common idiopathic BOOP, progressive BOOP characterized by acute respiratory distress syndrome is rare but is aggressive in its clinical course, leading to death.

Bibliography is available at Expert Consult.

Figure 394-3 **Follicular bronchiolitis in a 3 yr old girl with mosaic attenuation and cylindrical bronchiectasis.** CT findings suggested BO, but a biopsy documented the presence of follicular bronchiolitis. *(From Long FR, Druhan SM, Kuhn JP. 394.2 Follicular Bronchitis

Steven R. Boas

Follicular bronchitis is a lymphoproliferative lung disorder characterized by the presence of lymphoid follicles alongside the airways (bronchi or bronchioles) and infiltration of the walls of bronchi and bronchioles. Although the cause is unknown, an infectious etiology (viral, *L. pneumophila;* see Chapter 208) has been proposed. This disorder has been reported following lung transplant and in an HIV-positive child. It can occur in adults and children; in children, onset of symptoms generally occurs by 6 wk of age and peaks between 6 and 18 mo. Cough, moderate respiratory distress, fever, and fine crackles are common clinical findings. Fine crackles generally persist over time, and recurrence of symptoms is common. Chest radiographs may be relatively benign initially (air trapping, peribronchial thickening) but evolve into the typical interstitial pattern. Chest CT can show a fine reticular pattern as well as bronchiectasis and centrilobular branching but can also appear normal (see Table 394-2). Definitive diagnosis is made by open-lung biopsy (Fig. 394-3). Some patients with follicular bronchitis respond to therapy with corticosteroids. Prognosis is variable, with some patients having significant progression of pulmonary

disease and others developing only mild obstructive airway disease. In children it is generally associated with immunodeficiency; the differential diagnosis includes the pulmonary complications of HIV infection (see Chapter 276).

Bibliography is available at Expert Consult.

394.3 Pulmonary Alveolar Microlithiasis

Steven R. Boas

Pulmonary alveolar microlithiasis (PAM) is a rare disease characterized by the formation of lamellar concretions of calcium phosphate or "microliths" within the alveoli, creating a classic pattern on the radiograph (Fig. 394-4).

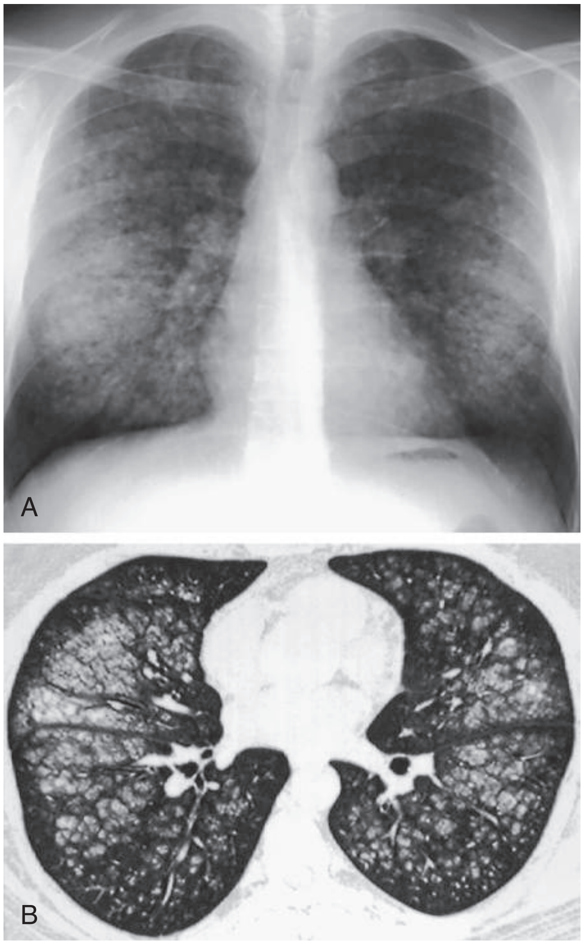

Figure 394-4 Radiographic features of pulmonary alveolar microlithiasis. **A,** Posteroanterior chest radiograph showing the classic "sandstorm" appearance of pulmonary alveolar microlithiasis, including diffuse, patchy, bilateral sharp micronodular disease. **B,** High-resolution CT scan of the chest showing micronodular densities. *(From Brandenburg VM, Schubert H. Images in clinical medicine. Pulmonary alveolar microlithiasis.* N Engl J Med *348:1555, 2003.)*

EPIDEMIOLOGY AND ETIOLOGY

Although the mean age at time of diagnosis is in the mid 30s, the onset of the disease can occur in childhood. PAM is inherited in an autosomal recessive pattern. In 2006, a mutation in the gene that encodes for the type IIb sodium-phosphate cotransporter protein (SCL34A2) was discovered in people with PAM. This gene is expressed in high levels in the lungs predominantly in type 2 epithelial cells. While the precise role of this protein is unknown, it is speculated that it helps remove phosphate from the alveolar space as well as a phosphate regular in other organs.

In some families, progression of disease is rapid. An equal male and female incidence is noted. Although PAM is found throughout the world, there is a high incidence in Turkey and a lesser incidence in Italy, Japan, and India.

CLINICAL MANIFESTATIONS

When symptomatic, patients with PAM usually complain of dyspnea on exertion and nonproductive cough. Physical examination of the lungs can reveal fine inspiratory crackles and diminished breath sounds. Clubbing occurs, although this is usually a more advanced sign. Discordance between the clinical and radiographic manifestations is common. Many children are often asymptomatic on initial presentation and present with symptoms during adulthood. Complications of pneumothorax, pleural adhesions and calcifications, pleural fibrosis, apical bullae, and extrapulmonary sites of microliths have been reported (kidneys, prostate, sympathetic chain, and testes).

DIAGNOSIS

Chest radiography typically reveals bilateral infiltrates with a fine micronodular appearance or **sandstorm** appearance with greater density in the lower and middle lung fields (see Fig. 394-4). CT of the chest shows diffuse micronodular calcified densities, with thickening of the microliths along the septa and around distal bronchioles, especially in the inferior and posterior regions (see Table 394-2). Diffuse uptake of technetium-99 methylene diphosphonate by nuclear scan has been reported. Open lung and transbronchial lung biopsy reveal 0.1-0.3 mm laminated calcific concretions within the alveoli. Although the alveoli are often normal initially, progression to pulmonary fibrosis with advancing disease usually ensues. Sputum expectoration might reveal small microliths, although this finding is not diagnostic for PAM and is not typically seen in children. Detection of calcium deposits in bronchoalveolar lavage fluid on bronchoscopy supports the diagnosis. Pulmonary function testing reveals restrictive lung disease with impaired diffusing capacity as the disease progresses, whereas exercise testing demonstrates arterial oxygen desaturation. Detection of a mutation in the *SCL34A2* gene confirms the diagnosis. The differential diagnosis includes sarcoidosis, miliary tuberculosis, hemosiderosis, healed disseminated histoplasmosis, pulmonary calcinosis, and metastatic pulmonary calcifications.

TREATMENT

No specific treatment is effective, although some clinicians have used glucocorticosteroids, etidronate disodium, and bronchopulmonary lavage with limited success. Lung transplantation has been performed for this condition, although it is unknown whether the disease recurs after transplantation.

PROGNOSIS

Progressive cardiopulmonary disease can ensue, leading to cor pulmonale, superimposed infections, and subsequent death in mid-adulthood. Because of the familial nature of this disease, counseling and chest radiographs of family members are indicated.

Chapter 395

Congenital Disorders of the Lung

395.1 Pulmonary Agenesis and Aplasia

Joshua A. Blatter and Jonathan D. Finder

ETIOLOGY AND PATHOLOGY

Pulmonary agenesis differs from hypoplasia in that agenesis entails the complete absence of a lung. Agenesis differs from aplasia by the absence of a bronchial stump or carina that is seen in aplasia. Bilateral pulmonary agenesis is incompatible with life, manifesting as severe respiratory distress and failure. Pulmonary agenesis is thought to be an autosomal recessive trait, with an estimated incidence of 1 in 10,000-15,000 births.

CLINICAL MANIFESTATIONS AND PROGNOSIS

Unilateral agenesis or hypoplasia can have few symptoms and nonspecific findings, resulting in only 33% of the cases being diagnosed while the patient is living. Symptoms tend to associated with central airway complications of compression, stenosis, and/or tracheobronchomalacia. In patients in whom the right lung is absent, the aorta can compress the trachea and lead to symptoms of central airway compression. Right lung agenesis has a higher morbidity and mortality than left lung agenesis. Pulmonary agenesis is often seen in association with other congenital anomalies such as the **VACTERL sequence** (*v*ertebral anomalies, *a*nal atresia, *c*ongenital heart disease, *t*racheoesophageal fistula, *r*enal anomalies, and *l*imb anomalies), ipsilateral facial and skeletal malformations, and central nervous system and cardiac malformations. Compensatory growth of the remaining lung allows improved gas exchange, but the mediastinal shift can lead to scoliosis and airway compression. Scoliosis can result from unequal thoracic growth.

DIAGNOSIS AND TREATMENT

Chest radiographic findings of unilateral lung or lobar collapse with a shift of mediastinal structures toward the affected side can prompt referral for suspected foreign-body aspiration, mucous plug occlusion, or other bronchial mass lesions. The diagnosis requires a high index of suspicion to avoid the unnecessary risks of bronchoscopy, including potential perforation of the rudimentary bronchus. CT of the chest is diagnostic, although the diagnosis may be suggested by chronic changes in the contralateral aspect of the chest wall and lung expansion on chest radiographs. Because pulmonary agenesis can be associated with a wide variety of congenital lesions, whole-body MRI can be useful to determine whether other systems (e.g., cardiac, gastrointestinal) are affected. Conservative treatment is usually recommended, although surgery has offered benefit in selected cases.

Bibliography is available at Expert Consult.

395.2 Pulmonary Hypoplasia

Joshua A. Blatter and Jonathan D. Finder

ETIOLOGY AND PATHOLOGY

Pulmonary hypoplasia involves a decrease in both the number of alveoli and the number of airway generations. The hypoplasia may be bilateral in the setting of bilateral lung constraint, as in oligohydramnios or thoracic dystrophy. Pulmonary hypoplasia is usually secondary to other intrauterine disorders that produce an impairment of normal lung development (see Chapter 101). Conditions such as deformities of the thoracic spine and rib cage (thoracic dystrophy), pleural effusions with fetal hydrops, congenital pulmonary airway malformation, and congenital diaphragmatic hernia physically constrain the developing lung. Any condition that produces oligohydramnios (fetal renal insufficiency or prolonged premature rupture of membranes) can also lead to diminished lung growth. In these conditions, airway and arterial branching are inhibited, thereby limiting the capillary surface area. Large unilateral lesions, such as congenital diaphragmatic hernia or pulmonary airway malformation, can displace the mediastinum and thereby produce a contralateral hypoplasia, although usually not as severe as that seen on the ipsilateral side.

CLINICAL MANIFESTATIONS

Pulmonary hypoplasia is usually recognized in the newborn period, owing to either the respiratory insufficiency or the presentation of persistent pulmonary hypertension (see Chapter 101.7). Later presentation (tachypnea) with stress or respiratory viral infection can be seen in infants with mild pulmonary hypoplasia.

DIAGNOSIS AND TREATMENT

A variety of imaging techniques, including MRI and ultrasound, with estimation of oligohydramnios, can be helpful to identify hypoplasia, but not to predict pulmonary function. Mechanical ventilation and oxygen may be required to support gas exchange. Specific therapy to control associated pulmonary hypertension, such as inhaled nitric oxide, may be useful. In cases of severe hypoplasia, the limited capacity of the lung for gas exchange may be inadequate to sustain life. Extracorporeal membrane oxygenation can provide gas exchange for a critical period of time and permit survival. Rib-expanding devices (vertically expansible prosthetic titanium ribs) can improve the survival of patients with thoracic dystrophies (see Chapter 700).

Bibliography is available at Expert Consult.

395.3 Congenital Cystic Malformation

Joshua A. Blatter and Jonathan D. Finder

PATHOLOGY

Congenital pulmonary airway malformation (CPAM), formerly known as cystic adenomatoid malformation, consists of hamartomatous or dysplastic lung tissue mixed with more normal lung, generally confined to 1 lobe. This congenital pulmonary disorder occurs in approximately 1-4 in 100,000 births. Prenatal ultrasonographic findings are classified as **macrocystic** (single or multiple cysts >5 mm) or **microcystic** (echogenic cysts <5 mm). Five histologic patterns have been described. **Type 0** (acinar dysplasia) is least common (<3%) and consists of microcystic disease throughout the lungs. The prognosis is poorest for this type, and infants die at birth. **Type 1** (60%) is macrocystic and consists of a single or several large (>2 cm in diameter) cysts lined with ciliated pseudostratified epithelium; the lesion is localized involving only a part of 1 lobe. One-third of cases have mucus-secreting cells. Presentation is in utero or in the newborn period. Cartilage is rarely seen in the wall of the cyst. This type has a good prognosis for survival. **Type 2** (20%) is microcystic and consists of multiple small cysts with histology similar to that of the type 1 lesion. Type 2 is associated with other serious congenital anomalies (renal, cardiac, diaphragmatic hernia) and carries a poor prognosis. **Type 3** (<10%) is seen mostly in males; the lesion is a mixture of microcysts and solid tissue with bronchiole-like structures lined with cuboidal ciliated epithelium and separated by areas of nonciliated cuboidal epithelium. The prognosis for this type, like type 0, is poor. **Type 4** (10%) is commonly macrocystic and lacks mucus cells. It is associated with malignancy

(pleuropulmonary blastoma) and can present either in childhood or in asymptomatic adults.

ETIOLOGY

The lesion probably results from an embryologic injury before the 35th day of gestation, with maldevelopment of terminal bronchiolar structures. Histologic examination reveals little normal lung and many glandular elements. Cysts are very common; cartilage is rare. The presence of cartilage might indicate a somewhat later embryologic insult, perhaps extending into the 10th-24th wk. Although growth factor interactions and signaling mechanisms have been implicated in altered lung-branching morphogenesis, the exact roles in the maldevelopment seen here remain obscure.

DIAGNOSIS

Cystic airway malformations can be diagnosed in utero by ultrasonography (Fig. 395-1). Fetal cystic lung abnormalities can include CPAM (40%), pulmonary sequestration (14%) (see Chapter 395.4), or both (26%); the median age at diagnosis is usually 21 wk gestation. In 1 series, only 7% had severe signs of fetal distress including hydrops, pleural effusion, polyhydramnios, ascites, or severe facial edema; 96% of the fetuses were born alive, 2 of whom died in the neonatal period. Lesions causing fetal hydrops have a poor prognosis. Large lesions, by compressing adjacent lung, can produce pulmonary hypoplasia in nonaffected lobes (see Chapter 395.2). Even lesions that appear large in early gestation can regress considerably or decrease in relative size and be associated with good pulmonary function in childhood. CT allows accurate diagnosis and sizing of the lesion and is indicated even in asymptomatic neonates.

CLINICAL MANIFESTATIONS

Patients can present in the newborn period or early infancy with respiratory distress, recurrent respiratory infection, and pneumothorax. The lesion may be confused with a diaphragmatic hernia (see Chapter 101.8). Patients with smaller lesions are usually asymptomatic until mid-childhood, when episodes of recurrent or persistent pulmonary infection or chest pain occur. Breath sounds may be diminished, with mediastinal shift away from the lesion on physical examination. Chest radiographs reveal a cystic mass, sometimes with mediastinal shift (Fig. 395-2). Occasionally, an air–fluid level suggests a lung abscess (see Chapter 402).

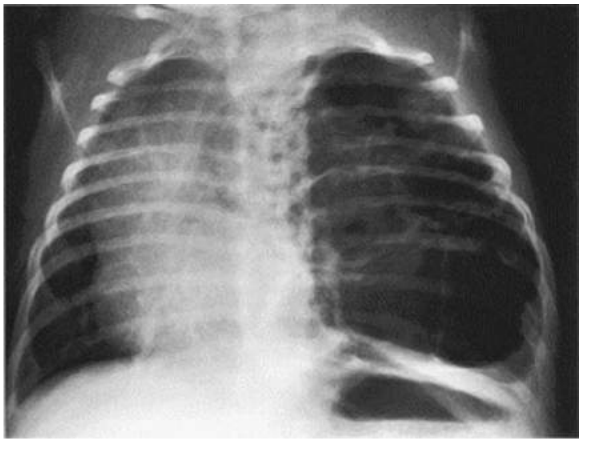

Figure 395-2 Neonatal chest x-ray showing large multicystic mass in the left hemithorax with mediastinal shift as a result of congenital pulmonary airway malformation (CPAM). *(From Williams HJ, Johnson KJ: Imaging of congenital cystic lung lesions,* Paediatr Respir Rev *3:120–127, 2002.)*

TREATMENT

Antenatal intervention in severely affected infants is controversial but can include excision of the affected lobe for microcystic lesions, aspiration of macrocystic lesions, and, rarely, open fetal surgery. In the postnatal period, surgery is indicated for symptomatic patients. Although surgery may be delayed for asymptomatic infants because postnatal resolution has been reported, true resolution appears to be very rare in that abnormalities usually remain detectable on CT or MRI. Sarcomatous and carcinomatous degeneration have been described in patients with CPAM, so surgical resection by 1 year of age is recommended to limit malignant potential. The mortality rate is <10%. Another indication for surgery is to rule out **pleuropulmonary**

blastoma, a malignancy that can appear radiographically similar to type I CPAM.

395.4 Pulmonary Sequestration

Joshua A. Blatter and Jonathan D. Finder

Pulmonary sequestration is a congenital anomaly of lung development that can be intrapulmonary or extrapulmonary, according to the location within the visceral pleura. The majority of sequestrations are intrapulmonary.

PATHOPHYSIOLOGY

The lung tissue in a sequestration does not connect to a bronchus and receives its arterial supply from the systemic arteries (commonly off the aorta) and returns its venous blood to the right side of the heart through the inferior vena cava (**extralobar**) or pulmonary veins (**intralobar**). The sequestration functions as a space-occupying lesion within the chest; it does not participate in gas exchange and does not lead to a left-to-right shunt or alveolar dead space. Communication with the airway can occur as the result of rupture of infected material into an adjacent airway. Collateral ventilation within intrapulmonary lesions via pores of Kohn can occur. Pulmonary sequestrations can arise through the same pathoembryologic mechanism as a remnant of a diverticular outgrowth of the esophagus. Some propose that intrapulmonary sequestration is an acquired lesion primarily caused by infection and inflammation; inflammation leads to cystic changes and hypertrophy of a feeding systemic artery. This is consistent with the rarity of this lesion in autopsy series of newborns. Gastric or pancreatic tissue may be found within the sequestration. Cysts also may be present. Other associated congenital anomalies, including CPAM (see Chapter 395.3), diaphragmatic hernia (see Chapter 101.8), and esophageal cysts, are not uncommon. Some believe that intrapulmonary sequestration is often a manifestation of CPAM and have questioned the existence of intrapulmonary sequestration as a separate entity.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Physical findings in patients with sequestration include an area of dullness to percussion and decreased breath sounds over the lesion. During infection, crackles may also be present. A continuous or purely systolic murmur may be heard over the back. If findings on routine chest radiographs are consistent with the diagnosis, further delineation is indicated before surgical intervention (Fig. 395-3). CT with contrast can demonstrate both the extent of the lesion and its vascular supply. MR angiography is also useful. Ultrasonography can help rule out a diaphragmatic hernia and demonstrate the systemic artery. Surgical removal is recommended. Identifying the blood supply before surgery avoids inadvertently severing its systemic artery. Coil embolization (transumbilical in neonates; arterial in older patients) has been successful in treating patients with sequestration.

Intrapulmonary sequestration is generally found in a lower lobe and does not have its own pleura. Patients usually present with infection. In older patients, hemoptysis is common. A chest radiograph during a period when there is no active infection reveals a mass lesion; an air–fluid level may be present. During infection, the margins of the lesion may be blurred. There is no difference in the incidence of this lesion in each lung.

Extrapulmonary sequestration is much more common in boys, and almost always involves the left lung. This lesion is enveloped by a pleural covering and is associated with diaphragmatic hernia and other abnormalities such as colonic duplication, vertebral abnormalities, and pulmonary hypoplasia. Many of these patients are asymptomatic when the mass is discovered by routine chest radiography. Other patients present with respiratory symptoms or heart failure. Subdiaphragmatic extrapulmonary sequestration can manifest as an abdominal mass on prenatal ultrasonography. The advent of prenatal ultrasonography has also enabled evidence that fetal pulmonary sequestrations can spontaneously regress.

TREATMENT

Treatment of intrapulmonary sequestration is surgical removal of the lesion, a procedure that usually requires excision of the entire involved lobe. Segmental resection occasionally suffices. Surgical resection of the involved area is recommended for extrapulmonary sequestration. Coil embolization of the feeding artery has also been successful.

Bibliography is available at Expert Consult.

395.5 Bronchogenic Cysts

Joshua A. Blatter and Jonathan D. Finder

ETIOLOGY AND PATHOLOGY

Bronchogenic cysts arise from abnormal budding of the tracheal diverticulum of the foregut before the 16th wk of gestation and are originally lined with ciliated epithelium. They are more commonly found on the right and near a midline structure (trachea, esophagus, carina), but peripheral lower lobe and perihilar intrapulmonary cysts are not

infrequent. Diagnosis may be precipitated by enlargement of the cyst, which causes symptoms by pressure on an adjacent airway. When the diagnosis is delayed until an infection occurs, the ciliated epithelium may be lost, and accurate pathologic diagnosis is then impossible. Cysts are rarely demonstrable at birth. Later, some cysts become symptomatic by becoming infected or by enlarging and compromising the function of an adjacent airway.

CLINICAL MANIFESTATIONS AND TREATMENT

Fever, chest pain, and productive cough are the most common presenting symptoms. Dysphagia may be present; some bronchogenic cysts are asymptomatic. A chest radiograph reveals the cyst, which can contain an air–fluid level (Fig. 395-4). CT scan or MRI is obtained in most cases to better demonstrate anatomy and extent of lesion before surgical resection. Treatment of symptomatic cysts is surgical excision after appropriate antibiotic management. Asymptomatic cysts are generally excised in view of the high rate of infection.

Bibliography is available at Expert Consult.

395.6 Congenital Pulmonary Lymphangiectasia

Joshua A. Blatter and Jonathan D. Finder

ETIOLOGY AND PATHOLOGY

Congenital pulmonary lymphangiectasia is characterized by greatly dilated lymphatic ducts throughout the lung. It can occur in 3 pathologic circumstances: **pulmonary venous obstruction** that produces an elevated transvascular pressure and engorges the pulmonary lymphatics; **generalized lymphangiectasia**, as a generalized disease of several organ systems, including lungs and the intestines (can be associated with Noonan syndrome); and **primary lymphangiectasia** limited to the lung as a manifestation of an abnormality in lymphatic development.

CLINICAL MANIFESTATIONS AND TREATMENT

Children with pulmonary venous obstruction or severe pulmonary lymphangiectasia present with dyspnea and cyanosis in the newborn period. Hydrops fetalis may be diagnosed antenatally. Chest radiographs reveal diffuse, dense, reticular densities with prominence of Kerley B lines. Pleural effusions are common; thoracentesis will reveal chylothorax in this setting. If the lung is not completely involved, the spared areas appear hyperlucent. Respiration is compromised because of impaired diffusion and decreased pulmonary compliance. The diagnosis can be suggested by CT scan and/or cardiac catheterization; definitive diagnosis requires lung biopsy (either thoracoscopic or open).

Treatment is supportive and includes administration of oxygen, mechanical ventilation, nutritional support (including gastrostomy placement and use of feedings containing medium-chain triglycerides), and careful fluid management with diuretics. Primary pulmonary lymphangiectasia can produce severe pulmonary dysfunction that can require long-term mechanical ventilation; long-term survival and resolution of respiratory insufficiency is possible even in severe cases. Occasionally, the pulmonary venous obstruction is secondary to left-sided cardiac lesions; relief of the latter can produce improvement in pulmonary dysfunction. Generalized lymphangiectasia produces milder pulmonary dysfunction, and survival to mid-childhood and beyond is not unusual.

Bibliography is available at Expert Consult.

395.7 Lung Hernia

Joshua A. Blatter and Jonathan D. Finder

ETIOLOGY AND PATHOLOGY

A lung hernia is a protrusion of the lung beyond its normal thoracic boundaries. Approximately 20% are congenital, with the remainder being noted after chest trauma or thoracic surgery or in patients with pulmonary diseases such as cystic fibrosis (see Chapter 403) or asthma (see Chapter 144), which cause frequent cough and generate high intrathoracic pressure. A congenital weakness of the suprapleural membrane (Sibson fascia) or musculature of the neck can play a role in the appearance of a lung hernia. More than half of congenital lung hernias and almost all acquired hernias are **cervical.** Congenital cervical hernias usually occur anteriorly through a gap between the scalenus anterior and sternocleidomastoid muscles. Cervical herniation is usually prevented by the trapezius muscle (posteriorly, at the thoracic inlet) and by the 3 scalene muscles (laterally).

CLINICAL MANIFESTATIONS AND TREATMENT

The presenting sign of a cervical hernia (Sibson hernia) is usually a neck mass noticed while straining or coughing. Some lesions are asymptomatic and detected only when a chest film is taken for another reason. Findings on physical examination are normal except during Valsalva maneuver, when a soft bulge may be noticed in the neck. In most cases, no treatment is necessary, although these hernias can cause problems during attempts to place a central venous catheter through the jugular or subclavian veins. They can resolve spontaneously.

Paravertebral or parasternal hernias are usually associated with rib anomalies. Intercostal hernias usually occur parasternally, where the external intercostal muscle is absent. Posteriorly, despite the seemingly inadequate internal intercostal muscle, the paraspinal muscles usually prevent herniation. Straining, coughing, or playing a musical

instrument can have a role in causing intercostal hernias, but in most cases, there is probably a preexisting defect in the thoracic wall.

Surgical treatment for lung hernia is occasionally justified for cosmetic reasons. In patients with severe chronic pulmonary disease and chronic cough and for whom cough suppression is contraindicated, permanent correction might not be achieved.

BRONCHOBILIARY FISTULA

A bronchobiliary fistula consists of a fistulous connection between the right middle lobe bronchus and the left hepatic ductal system. Although diagnosis can be delayed until adulthood, this rare anomaly typically manifests with life-threatening bronchopulmonary infections in early infancy. Girls are more commonly affected. *Definitive diagnosis* requires endoscopy or exploratory surgery. *Treatment* includes surgical excision of the entire intrathoracic portion of the fistula. If the hepatic portion of the fistula does not communicate with the biliary system or duodenum, the involved segment might also have to be resected. Bronchobiliary communications also occur as acquired lesions resulting from hepatic disease complicated by infection.

Table 396-1 Etiology of Pulmonary Edema

INCREASED PULMONARY CAPILLARY PRESSURE
Cardiogenic, such as left ventricular failure
Noncardiogenic, as in pulmonary venoocclusive disease, pulmonary venous fibrosis, mediastinal tumors
INCREASED CAPILLARY PERMEABILITY
Bacterial and viral pneumonia
Acute respiratory distress syndrome
Inhaled toxic agents
Circulating toxins
Vasoactive substances such as histamine, leukotrienes, thromboxanes
Diffuse capillary leak syndrome, as in sepsis
Immunologic reactions, such as transfusion reactions
Smoke inhalation
Aspiration pneumonia/pneumonitis
Drowning and near drowning
Radiation pneumonia
Uremia
LYMPHATIC INSUFFICIENCY
Congenital and acquired
DECREASED ONCOTIC PRESSURE
Hypoalbuminemia, as in renal and hepatic diseases, protein-losing states, and malnutrition
INCREASED NEGATIVE INTERSTITIAL PRESSURE
Upper airway obstructive lesions, such as croup and epiglottitis
Reexpansion pulmonary edema
MIXED OR UNKNOWN CAUSES
Neurogenic pulmonary edema
High-altitude pulmonary edema
Eclampsia
Pancreatitis
Pulmonary embolism
Heroin (narcotic) pulmonary edema

Chapter 396
Pulmonary Edema

Robert L. Mazor and Thomas P. Green

A sequela of several different pathologic processes, pulmonary edema is an excessive accumulation of fluid in the interstitium and air spaces of the lung resulting in oxygen desaturation, decreased lung compliance, and respiratory distress. The condition is common in the acutely ill child.

PATHOPHYSIOLOGY

Although pulmonary edema is traditionally separated into two categories according to cause (*cardiogenic* and *noncardiogenic*), the end result of both processes is a net fluid accumulation within the interstitial and alveolar spaces. Noncardiogenic pulmonary edema, in its most severe state, is also known as **acute respiratory distress syndrome** (see Chapters 71 and 373).

The hydrostatic pressure and colloid osmotic (oncotic) pressure on either side of a pulmonary vascular wall, along with vascular permeability, are the forces and physical factors that determine fluid movement through the vessel wall. Baseline conditions lead to a net filtration of fluid from the intravascular space into the interstitium. This "extra" interstitial fluid is usually rapidly reabsorbed by pulmonary lymphatics. Conditions that lead to altered vascular permeability, increased pulmonary vascular pressure, and decreased intravascular oncotic pressure increase the net flow of fluid out of the vessel (Table 396-1). Once the capacity of the lymphatics for fluid removal is exceeded, water accumulates in the lung.

To understand the sequence of lung water accumulation, it is helpful to consider its distribution among 4 distinct compartments, as follows:

- *Vascular compartment:* This compartment consists of all blood vessels that participate in fluid exchange with the interstitium. The vascular compartment is separated from the interstitium by capillary endothelial cells. Several endogenous inflammatory mediators, as well as exogenous toxins, are implicated in the pathogenesis of pulmonary capillary endothelial damage, leading to the "leakiness" seen in several systemic processes.
- *Interstitial compartment:* The importance of this space lies in its interposition between the alveolar and vascular compartments. As fluid leaves the vascular compartment, it collects in the interstitium before overflowing into the air spaces of the alveolar compartment.
- *Alveolar compartment:* This compartment is lined with type 1 and type 2 epithelial cells. These epithelial cells have a role in active fluid transport from the alveolar space, and they act as a barrier to exclude fluid from the alveolar space. The potential fluid volume of the alveolar compartment is many times greater than that of the interstitial space, perhaps providing another reason that alveolar edema clears more slowly than interstitial edema.

- *Pulmonary lymphatic compartment:* There is an extensive network of pulmonary lymphatics. Excess fluid present in the alveolar and interstitial compartments is drained via the lymphatic system. When the capacity for drainage of the lymphatics is surpassed, fluid accumulation occurs.

ETIOLOGY

The specific clinical findings vary according to the underlying mechanism (see Table 396-1).

Transudation of fluid as a result of increased pulmonary vascular pressure *(capillary hydrostatic pressure)* occurs in several cardiac processes. A significant left-to-right shunting lesion, such as a septal defect, leads to a pressure and volume load on the pulmonary vasculature. The resultant pulmonary edema is one of the hallmarks of congestive heart failure. Left ventricular failure, mitral valve disease, and pulmonary venous obstructive lesions cause increased "backpressure" in the pulmonary vasculature. This results in an increase in pulmonary capillary pressure.

Increased capillary permeability is usually secondary to endothelial damage. Such damage can occur secondary to direct injury to the alveolar epithelium or indirectly through systemic processes that deliver circulating inflammatory mediators or toxins to the lung. Inflammatory mediators (tumor necrosis factor, leukotrienes, thromboxanes) and vasoactive agents (nitric oxide, histamine) formed during pulmonary and systemic processes potentiate the altered capillary permeability that occurs in many disease processes, with sepsis being a common cause.

Fluid homeostasis in the lung largely depends on drainage via the lymphatics. Experimentally, pulmonary edema occurs with obstruction of the lymphatic system. Increased lymph flow and dilation of lymphatic vessels occur in chronic edematous states.

A decrease in intravascular oncotic pressure leads to pulmonary edema by altering the forces promoting fluid reentry into the vascular space. This occurs in dilutional disorders, such as fluid overload with hypotonic solutions, and in protein-losing states, such as nephrotic syndrome and malnutrition.

The excessive negative interstitial pressure seen in upper airway diseases, such as croup and laryngospasm, may promote pulmonary edema. Aside from the physical forces present in these diseases, other mechanisms may also be involved. Theories implicate an increase in CO_2 tension, decreased O_2 tension, and extreme increases in cardiac afterload, leading to transient cardiac insufficiency.

The mechanism causing neurogenic pulmonary edema is not clear. A massive sympathetic discharge secondary to a cerebral injury may produce increased pulmonary and systemic vasoconstriction, resulting in a shift of blood to the pulmonary vasculature, an increase in capillary pressure, and edema formation. Inflammatory mechanisms may also play a role by increasing capillary permeability.

The mechanism responsible for high-altitude pulmonary edema is unclear, but it may also be related to sympathetic outflow, increased pulmonary vascular pressures, and hypoxia-induced increases in capillary permeability (see Chapter 73).

Active ion transport followed by passive, osmotic water movement is important in clearing the alveolar space of fluid. There are some experimental data that β agonists and growth factors increase alveolar fluid removal. Interindividual genetic differences in the rates of these transport processes may be important in determining which individuals are susceptible to altitude-related pulmonary edema. Although the existence of these mechanisms suggests that therapeutic interventions may be developed to promote resolution of pulmonary edema, no such therapies currently exist.

CLINICAL MANIFESTATIONS

The clinical features depend on the mechanism of edema formation. In general, interstitial edema and alveolar edema prevent the inflation of alveoli, leading to atelectasis and decreased surfactant production. This results in diminished pulmonary compliance and tidal volume. The patient must increase respiratory effort and/or the respiratory rate so as to maintain minute ventilation. The earliest clinical signs of pulmonary edema include increased work of breathing, tachypnea, and dyspnea. As fluid accumulates in the alveolar space, auscultation reveals fine crackles and wheezing, especially in dependent lung fields. In cardiogenic pulmonary edema, a gallop may be present as well as peripheral edema and jugular venous distention.

Table 396-2 Radiographic Features That May Help Differentiate Cardiogenic from Noncardiogenic Pulmonary Edema

RADIOGRAPHIC FEATURE	CARDIOGENIC EDEMA	NONCARDIOGENIC EDEMA
Heart size	Normal or greater than normal	Usually normal
Width of the vascular pedicle*	Normal or greater than normal	Usually normal or less than normal
Vascular distribution	Balanced or inverted	Normal or balanced
Distribution of edema	Even or central	Patchy or peripheral
Pleural effusions	Present	Not usually present
Peribronchial cuffing	Present	Not usually present
Septal lines	Present	Not usually present
Air bronchograms	Not usually present	Usually present

*The width of the vascular pedicle in adults is determined by dropping a perpendicular line from the point at which the left subclavian artery exits the aortic arch and measuring across to the point at which the superior vena cava crosses the right mainstem bronchus. A vascular pedicle width >70 mm on a portable digital anteroposterior radiograph of the chest obtained when the patient is supine is optimal for differentiating high from normal-to-low intravascular volume.

From Ware LB, Matthay MA: Acute pulmonary edema, N Engl J Med *353:2788–2796, 2005.*

Chest radiographs can provide useful ancillary data, although findings of initial radiographs may be normal. Early radiographic signs that represent accumulation of interstitial edema include peribronchial and perivascular cuffing. Diffuse streakiness reflects interlobular edema and distended pulmonary lymphatics. Diffuse, patchy densities, the so-called butterfly pattern, represent bilateral interstitial or alveolar infiltrates and are a late sign. Cardiomegaly is often seen with cardiogenic causes of pulmonary edema. Heart size is usually normal in noncardiogenic pulmonary edema (Table 396-2). Chest tomography demonstrates edema accumulation in the dependent areas of the lung. As a result, changing the patient's position can alter regional differences in lung compliance and alveolar ventilation.

Measurement of **brain natriuretic peptide**, often elevated in heart disease, can help differentiate cardiac from pulmonary causes of pulmonary edema. A brain natriuretic peptide level >500 pg/mL suggests heart disease; a level <100 pg/mL suggests lung disease.

TREATMENT

The treatment of a patient with noncardiogenic pulmonary edema is largely supportive, with the primary goal to ensure adequate ventilation and oxygenation. Additional therapy is directed toward the underlying cause. Patients should receive supplemental oxygen to increase alveolar oxygen tension and pulmonary vasodilation. Patients with pulmonary edema of cardiogenic causes should be managed with diuretics, inotropic agents and systemic vasodilators to reduce left ventricular afterload (see Chapter 442). Diuretics are also valuable in the treatment of pulmonary edema associated with total body fluid overload (sepsis, renal insufficiency). Morphine is often helpful as a vasodilator and a mild sedative.

Positive airway pressure improves gas exchange in patients with pulmonary edema. In tracheally intubated patients, positive end-expiratory pressure can be used to optimize pulmonary mechanics. Noninvasive forms of ventilation, such as mask or nasal prong

continuous positive airway pressure, are also effective. The mechanism by which positive airway pressure improves pulmonary edema is not entirely clear but is not associated with decreasing lung water. Rather, continuous positive airway pressure prevents complete closure of alveoli at the low lung volumes present at the end of expiration. It may also recruit already collapsed alveolar units. This leads to increased functional residual capacity and improved pulmonary compliance, improved surfactant function, and decreased pulmonary vascular resistance. The net effect is to decrease the work of breathing, improve oxygenation, and decrease cardiac afterload.

When mechanical ventilation becomes necessary, especially in noncardiogenic pulmonary edema, care must be taken to minimize the risk of development of complications from barotrauma, including pneumothorax, pneumomediastinum, and primary alveolar damage (see Chapter 71.1). Lung protective strategies include setting low tidal volumes, relatively high positive end-expiratory pressure, and allowing for permissive hypercapnia.

High-altitude pulmonary edema should be managed with altitude descent and supplemental oxygen. Portable continuous positive airway pressure or a portable hyperbaric chamber is also helpful. Nifedipine (10 mg initially, and then 20-30 mg by slow release every 12-24 hr) in adults is also helpful. If there is a history of high-altitude pulmonary edema, nifedipine and β-adrenergic agonists (inhaled) may prevent recurrence (see Chapter 73).

Chapter 397
Aspiration Syndromes
John L. Colombo

Aspiration of material that is foreign to the lower airway produces a varied clinical spectrum ranging from an asymptomatic condition to acute life-threatening events, such as occur with massive aspiration of gastric contents or hydrocarbon products. Other chapters discuss mechanical obstruction of large- or intermediate-size airways as occurs with foreign bodies (see Chapter 387) and infectious complications of aspiration and recurrent microaspiration (see Chapter 398), such as may occur with gastroesophageal reflux (see Chapter 323.1) or dysphagia (see Chapter 306). Occult aspiration of nasopharyngeal secretions into the lower respiratory tract is a normal event in healthy people, usually without apparent clinical significance.

GASTRIC CONTENTS

Aspiration of substantial amounts of gastric contents typically occurs in the context of vomiting. It is an infrequent complication of general anesthesia, gastroenteritis, or altered level of consciousness. Among 63,180 pediatric patients undergoing general anesthesia, 24 cases of aspiration occurred, but symptoms developed in only 9. Pathophysiologic consequences can vary, depending primarily on the pH and volume of the aspirate and the amount of particulate material. Increased clinical severity is noted with volumes greater than approximately 0.8 mL/kg and/or pH <2.5. Hypoxemia, hemorrhagic pneumonitis, atelectasis, intravascular fluid shifts, and pulmonary edema all occur rapidly after massive aspiration. These occur earlier, become more severe, and last longer with acid aspiration. Most clinical changes are present within minutes to 1-2 hr after the aspiration event. In the next 24-48 hr, there is a marked increase in lung parenchymal neutrophil infiltrations, mucosal sloughing, and alveolar consolidation that often correlates with increasing infiltrates on chest radiographs. These changes tend to occur significantly later and are more prolonged after aspiration of particulate material. Although infection usually does not have a role in initial lung injury after aspiration of gastric contents, aspiration may impair pulmonary defenses, predisposing the patient to secondary bacterial pneumonia. In the patient who has shown clinical improvement but then demonstrates clinical worsening, especially with fever and leukocytosis, secondary bacterial pneumonia should be suspected.

Treatment

If large-volume or highly toxic substance aspiration occurs in a patient who already has an artificial airway in place, it is important to perform immediate suctioning of the airway. If immediate suctioning cannot be performed, later suctioning or bronchoscopy is usually of limited therapeutic value except when there is suspicion of significant particulate aspiration. Attempts at acid neutralization are not warranted because acid is rapidly neutralized by the respiratory epithelium. Patients in whom large-volume or toxic aspiration is suspected should be observed, should undergo oxygenation measurement by oximetry or blood gas analysis, and should undergo a chest radiograph, even if they are asymptomatic. If the chest radiograph findings and oxygen saturation are normal, and the patient remains asymptomatic, home observation, after a period of observation in the hospital or office, is adequate. No treatment is indicated at that time, but the caregivers should be instructed to bring the child back in for medical attention should respiratory symptoms or fever develop. For patients who present with abnormal findings or in whom such findings develop during observation, oxygen therapy is given to correct hypoxemia. Endotracheal intubation and mechanical ventilation are often necessary for more severe cases. Bronchodilators may be tried, although they are usually of limited benefit. Animal studies indicate that treatment with corticosteroids does not provide benefit, unless given nearly simultaneously with the aspiration event; use of these agents may increase the risk of secondary infection. Prophylactic antibiotics are not indicated, although in the patient with limited reserve, early antibiotic coverage may be appropriate. If used, antibiotics that cover for anaerobic microbes should be considered. If the aspiration event occurs in a hospitalized or chronically ill patient, coverage of *Pseudomonas*, *Staphylococcus aureus,* and enteric Gram-negative organisms should also be considered. If empiric antibiotics are given, they should be discontinued when cultures and course warrant. A mortality rate of ≤5% is seen if 3 or fewer lobes are involved. Unless complications develop, such as infection or barotrauma, most patients recover in 2-3 wk. Prolonged lung damage may persist, including scarring, bronchiolitis obliterans, and bronchiectasis.

Prevention

Prevention of aspiration should always be the goal when airway manipulation is necessary for intubation or other invasive procedures. Feeding with enteral tubes passed beyond the pylorus, elevating the head of the bed 30-45 degrees in mechanically ventilated patients, and oral decontamination reduce the incidence of aspiration complications in the intensive care unit. Minimizing use of sedation, monitoring for gastric residuals, and gastric acid suppression may all help prevent aspiration. However, the latter is not without some controversy. Any patient with altered consciousness, especially one who is receiving tube feedings, should be considered at high risk for aspiration. Preoperative restriction of oral fluids to otherwise normal children for 6 hr does not appear to provide benefit compared to restriction for only 2 hr in terms of risk for aspiration.

HYDROCARBON ASPIRATION

Aspiration and resulting pneumonitis are typically the most dangerous consequences of acute hydrocarbon ingestion (see Chapter 63). Although significant pneumonitis occurs in <2% of all hydrocarbon ingestions, an estimated 20 deaths occur annually from hydrocarbon aspiration in both children and adults. Some of these deaths represent suicides. Hydrocarbons with lower surface tensions (gasoline,

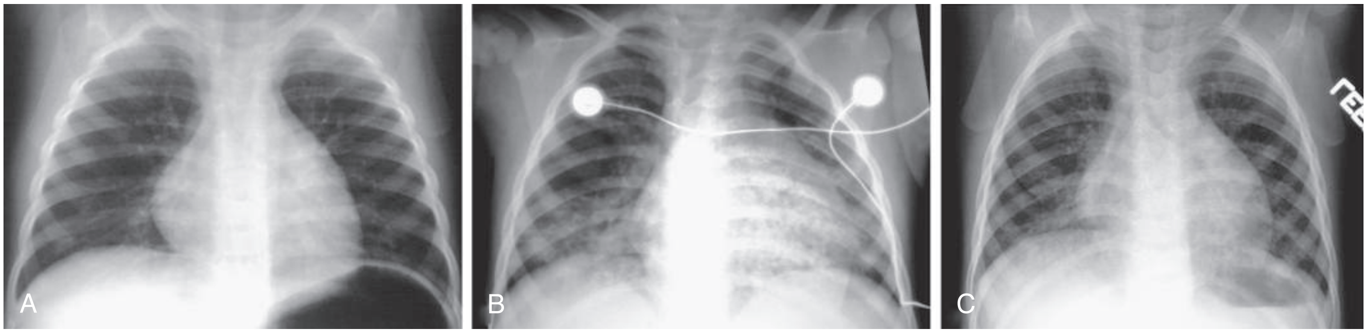

Figure 397-1 Chest radiographs of a 17 mo old who ingested furniture polish. **A,** Three hours after ingestion, the lungs are clear. **B,** At 24 hr, there are bibasilar coalescing nodular opacities. **C,** Three days later there is much clearing. *(From Slovis TL, editor:* Caffey's pediatric diagnostic imaging, *ed 11, Philadelphia, 2008, Mosby, p. 1287.)*

turpentine, naphthalene) have more potential for aspiration toxicity than heavier mineral or fuel oils. Ingestion of >30 mL (approximate volume of an adult swallow) of hydrocarbon is associated with an increased risk of severe pneumonitis. Clinical findings including chest retractions, grunting, cough, and fever may occur as soon as 30 min after aspiration or may be delayed for several hours. Lung radiographic changes usually occur within 2-8 hr, peaking in 48-72 hr (Fig. 397-1). Pneumatoceles and pleural effusions may occur. Patients presenting with cough, shortness of breath, or hypoxemia are at high risk for pneumonitis. Persistent pulmonary function abnormalities can be present many years after hydrocarbon aspiration. Other organ systems, especially the liver, central nervous system, and heart, may suffer serious injury. Cardiac dysrhythmias may occur and may be exacerbated by hypoxia and acid–base or electrolyte disturbances.

Treatment

Gastric emptying is contraindicated in nearly all situations because the risk of aspiration is greater than any systemic toxicity. Treatment is generally supportive, consisting of oxygen, fluids, and ventilatory support, and rarely extracorporeal membrane oxygenation, as necessary. Exogenous surfactant administration has been described as helpful in case reports. The child who has no symptoms and normal chest radiograph findings should be observed for 6-8 hr to ensure safe discharge. Certain hydrocarbons have more inherent systemic toxicity. The pneumonic **CHAMP** refers collectively to the following hydrocarbons: ***c***amphor, ***h***alogenated carbons, ***a***romatic hydrocarbons, and those associated with ***m***etals and ***p***esticides. Patients who ingest these compounds in volumes >30 mL, such as might occur with intentional overdose, may benefit from gastric emptying. This is still a high-risk procedure that can result in further aspiration. If a cuffed endotracheal tube can be placed without inducing vomiting, this procedure should be considered, especially in the presence of altered mental status. Treatment of each case should be considered individually, with guidance from a poison control center.

Other substances that are particularly toxic and cause significant lung injury when aspirated or inhaled include baby powder, chlorine, shellac, beryllium, and mercury vapors. Repeated exposure to low concentrations of these agents can lead to chronic lung disease, such as interstitial pneumonitis and granuloma formation. Corticosteroids may help reduce fibrosis development and improve pulmonary function, although the evidence for this benefit is limited.

Chapter 398

Chronic Recurrent Aspiration

John L. Colombo

ETIOLOGY

Repeated aspiration of even small quantities of gastric, nasal, or oral contents can lead to recurrent bronchitis or bronchiolitis; recurrent pneumonia; atelectasis; wheezing; cough; apnea; and/or laryngospasm. Pathologic outcomes include granulomatous inflammation, interstitial inflammation, fibrosis, lipoid pneumonia, and bronchiolitis obliterans. Most cases clinically manifest as airway inflammation, and are rarely associated with significant morbidity. Table 398-1 lists underlying disorders that are frequently associated with recurrent aspiration. Oropharyngeal incoordination is reportedly the most common underlying problem associated with recurrent pneumonias in hospitalized children. In 2 reports, from 26-48% of such children were found to have dysphagia with aspiration as the underlying problem. Lipoid pneumonia may occur after the use of home/folk remedies involving oral or nasal administration of animal or vegetable oils to treat various childhood illnesses. Lipoid pneumonia has been reported as a complication of these practices in the Middle East, Asia, India, Brazil, and Mexico. The initial underlying disease, language barriers, and a belief that these are not "medications" may delay the diagnosis (see Chapter 4).

Gastroesophageal reflux disease (GERD; see Chapter 323) is also a common underlying finding that may predispose to recurrent respiratory disease, but it is less frequently associated with recurrent pneumonia than is dysphagia (see Chapter 323). GERD is associated with microaspiration and bronchiolitis obliterans in lung transplant recipients. Aspiration has also been observed in infants with respiratory symptoms but no other apparent abnormalities. Recurrent microaspiration has been reported in otherwise apparently normal newborns, especially premature infants. Aspiration is also a risk in patients suffering from acute respiratory illness from other causes, especially respiratory syncytial virus infection (see Chapter 260). Modified barium swallow and videofluoroscopy reveal silent aspiration in these patients. This finding emphasizes the need for a high degree of clinical suspicion for ongoing aspiration in a child with an acute respiratory illness, being fed enterally, who deteriorates unexpectedly.

DIAGNOSIS

Some underlying predisposing factors (see Table 398-1) are frequently clinically apparent but may require specific further evaluation. Initial

Table 398-1 Conditions Predisposing to Aspiration Lung Injury in Children

ANATOMICAL AND MECHANICAL
Tracheoesophageal fistula
Laryngeal cleft
Vascular ring
Cleft palate
Micrognathia
Macroglossia
Cysts, tumors
Achalasia
Esophageal foreign body
Tracheostomy
Endotracheal tube
Nasal or oral feeding tube
Collagen vascular disease (scleroderma, dermatomyositises)
Gastroesophageal reflux disease
Obesity
NEUROMUSCULAR
Altered consciousness
Immaturity of swallowing/Prematurity
Dysautonomia
Increased intracranial pressure
Hydrocephalus
Vocal cord paralysis
Cerebral palsy
Muscular dystrophy
Hypotonia
Myasthenia gravis
Guillain-Barré syndrome
Spinal muscular atrophy
Ataxia-telangiectasia
Cerebral vascular accident
MISCELLANEOUS
Poor oral hygiene
Gingivitis
Prolonged hospitalization
Gastric outlet or intestinal obstruction
Poor feeding techniques (bottle propping, overfeeding, inappropriate foods for toddlers)
Bronchopulmonary dysplasia
Viral infection/bronchiolitis

Figure 398-1 **Chest radiograph of a developmentally delayed 15 yr old with chronic aspiration of oral formula.** Note posterior (dependent areas) distribution with sparing of heart borders.

Figure 398-2 Chest CT scan of same patient as in Figure 398-1. Note lung consolidation in dependent regions is of similar density to subcutaneous fat.

assessment begins with a detailed history and physical examination. The caregiver should be asked about spitting, vomiting, arching, or epigastric discomfort in an older child; the timing of symptoms in relation to feedings; positional changes; and nocturnal symptoms, such as coughing and wheezing. It is important to remember that coughing or gagging may be minimal or absent in a child with a depressed cough or gag reflex. Observation of a feeding is an essential part of the exam when a diagnosis of recurrent aspiration is being considered. Particular attention should be given to nasopharyngeal reflux, difficulty with sucking or swallowing, and associated coughing and choking. Voice changes (wet voice) and noisy (wet) breathing should be noted. The oral cavity should be inspected for gross abnormalities and stimulated to assess the gag reflex. Drooling or excessive accumulation of secretions in the mouth suggests dysphagia. Lung auscultation may reveal transient crackles or wheezes after feeding, particularly in the dependent lung segments.

The diagnosis of recurrent microaspiration is challenging because of the lack of highly specific and sensitive tests (Table 398-2). A plain chest radiograph is the usual initial study for a child in whom recurrent aspiration is suspected. The classic findings of segmental or lobar infiltrates localized to dependent areas may be found (Fig. 398-1), but there are a wide variety of radiographic findings. These findings include diffuse infiltrates, lobar infiltrates, bronchial wall thickening, hyperinflation, and even no detectable abnormalities. CT scans, though generally not indicated to establish a diagnosis of aspiration, may show infiltrates with decreased attenuation suggestive of lipoid pneumonia (Fig. 398-2). A carefully performed barium esophagram is useful in looking for anatomic abnormalities such as vascular ring, stricture, hiatal hernia, and tracheoesophageal fistula. It also yields qualitative information about esophageal motility and, when extended, of gastric emptying. However, primarily because of the very short viewing time, the esophagram is quite insensitive and nonspecific for aspiration or GERD. A modified barium swallow study with videofluoroscopy (videofluoroscopic swallowing study) is generally considered the gold standard for evaluating the swallowing mechanism. This study is preferably done with the assistance of a pediatric feeding specialist and a caregiver in the attempt to simulate the usual feeding technique of the child. The child is seated in normal eating position, and various consistencies of barium or barium-impregnated foods are offered. This study is more sensitive for demonstrating aspiration than bedside assessment or a traditional barium swallow study. The sensitivity of the modified barium swallow study is such that it occasionally detects aspiration in patients without apparent respiratory abnormalities.

Table 398-2 Summary of Diagnostic Tests of Aspiration

EVALUATION	BENEFITS	LIMITATIONS
Chest radiograph	Inexpensive and widely available Assesses accumulation of injury over time	Insensitive to early subtle changes of lung injury
High-resolution CT	Sensitive in detecting lung injury, such as bronchiectasis, tree-in-bud opacities, and bronchial thickening Less radiation than conventional CT Assesses accumulation of injury over time	More radiation exposure than plain radiograph Expensive
Video swallow study	Evaluates all phases of swallowing Evaluates multiple consistencies Feeding recommendations made at time of study	Information limited if child consumes only small quantities Difficult to perform in child who has not been feeding by mouth Radiation exposure proportional to study duration Cannot be performed at bedside Limited evaluation of anatomy Evaluates 1 moment in time Expensive
FEES/with sensory testing	Ability to thoroughly evaluate functional anatomy Evaluates multiple consistencies Can assess risk of aspiration in non-orally feeding child; airway protective reflexes can be assessed Feeding recommendations made at time of study Visual feedback for caregivers Can be performed at bedside No radiation exposure	Blind to esophageal phase and actual swallow Invasive and may not represent physiological swallowing conditions Evaluates 1 moment in time Not widely available Expensive
BAL	Evaluates anatomy of entire upper and lower airways Samples the end-organ of damage Sample available for multiple cytological and microbiologic tests Widely available	Uncertainty regarding interpretation of lipid-laden macrophage index Index cumbersome to calculate Requires sedation or anesthesia Invasive Expensive
Esophageal pH monitoring	Current gold standard for diagnosis of Acid gastroesophageal reflux Established normative data in children	Blind to majority of reflux (nonacid) events Difficult to establish causal relationship between gastroesophageal reflux and aspiration Somewhat invasive Evaluates short time interval
Esophageal impedance monitoring	Likely gold standard for diagnosis of GERD with supraesophageal manifestations Able to detect acid and nonacid reflux events Detects proximal reflux events Able to evaluate for GERD without stopping medications	Lack of normative data for children Somewhat invasive Expensive and cumbersome to interpret Not widely available Evaluates short time interval
Gastroesophageal scintigraphy	Performed under physiologic conditions Low radiation exposure	Poor sensitivity May not differentiate between aspiration from dysphagia or GERD
Radionuclide salivagram	Child does not have to be challenged with food bolus Low radiation exposure	Unknown sensitivity Unknown relationship to disease outcomes Evaluates 1 moment in time
Dye studies	Can be constructed as screening test or confirmatory test Can evaluate aspiration of secretions or feeds Repeating over time allows for broader evaluation	Uncertainty in interpretation owing to variability of technique Can only be performed in children with tracheostomies
Other biomarkers (pepsin, bile acids) milk protein	Theoretical high specificity and sensitivity	Limited availability and standardization Variable results to date

BAL, bronchoalveolar lavage; FEES, fiberoptic-endoscopic evaluation of swallowing; GERD, gastroesophageal reflux disease.
Modified from Boesch RP, Daines C, Willging JP, et al: Advances in the diagnosis and management of chronic pulmonary aspiration in children, Eur Respir J *28:847–861, 2006; and Tutor JD, Gosa MM: Dysphagia and aspiration in children,* Pediatr Pulmonol *47(4):321–337, 2012.*

A gastroesophageal "milk" scintiscan offers theoretical advantages over a barium swallow in being more physiologic and giving a longer window of viewing than the barium esophagram for detecting aspiration and GERD. However, this study has been found to have a low sensitivity and provides relatively little anatomic detail. Another radionuclide scan termed the "salivagram" may also be useful to assess aspiration of esophageal contents. When this scan is performed by experienced personnel, its sensitivity appears to be comparable to that of the modified barium swallow study. The use of fiberoptic endoscopic evaluation of swallowing has been found useful in adult and some pediatric patients, to observe swallowing directly without radiation exposure. The child's reaction to placement of the endoscope may

alter the assessment of function, depending on level of comfort and cooperation.

Tracheobronchial aspirates can be examined for numerous entities to evaluate for aspiration. For patients with artificial airways, the use of an oral dye and visual examination of tracheal secretions is useful. This test should not be done on a chronic basis, such as in tube feedings, because of possible dye toxicity. In using this test acutely, the best method is to place a few drops of dye on the patient's tongue and perform subsequent suctioning of the airway over the next several minutes. Quantitation of lipid-laden alveolar macrophages from bronchial aspirates has been shown to be a sensitive test for aspiration in children, but false-positive tests occur, especially with endobronchial obstruction, use of intravenous lipids, sepsis, and pulmonary bleeding. Bronchial washings may also be examined for various food substances, including lactose, glucose, food fibers, and milk antigens, as well as pepsin. Specificity and sensitivity of these tests have not been well studied.

TREATMENT

If chronic aspiration is associated with another underlying medical condition, treatment should be directed toward that problem. The level of morbidity from respiratory problems should determine the level of intervention. Often milder dysphagia can be treated with alteration of feeding position, limiting texture of foods to those best tolerated on modified barium esophagram (usually thicker foods), or limiting quantity per feeding. Currently evidence is lacking regarding the advisability of restricting oral intake of water by children whose aspiration is largely of thin fluids. Nasogastric tube feedings can be utilized temporarily during periods of transient vocal cord dysfunction or other dysphagia. Postpyloric feedings may also be helpful, especially if gastroesophageal reflux is present, although this does not eliminate reflux. There are several surgical procedures that may be considered. Tracheostomy (see Chapter 385.1), although sometimes predisposing to aspiration, may provide overall benefit from improved bronchial hygiene and the ability to suction aspirated material. Use of a one-way (Passy-Muir) valve on a tracheostomy tube has been shown to improve swallowing. Fundoplication with gastrostomy or jejunostomy feeding tube will reduce the probability of gastroesophageal reflux-induced aspiration, but recurrent pneumonias often persist because of dysphagia and presumed aspiration of upper airway secretions. Medical treatment with anticholinergics, such as glycopyrrolate or scopolamine, may significantly reduce morbidity from salivary aspiration but often has side effects. Aggressive surgical intervention with salivary gland excision, ductal ligation, laryngotracheal separation, or esophagogastric disconnection can be considered in severe, unresponsive cases. Although usually reserved for the most severe cases, surgical therapy may significantly improve quality of life and ease of care for some patients.

Chapter 399

Immune and Inflammatory Lung Disease

399.1 Hypersensitivity Pneumonia

Kevin J. Kelly

Hypersensitivity pneumonia (HP), aptly called *extrinsic allergic alveolitis* because the inciting agent is almost uniformly inhaled from the environment, is a complex immunologic-mediated syndrome of the pulmonary alveoli and interstitium. There are numerous specific disease names based on the origin of the offending antigen that is inhaled to describe HP. Prompt recognition of the signs and symptoms allows for complete reversal of the disease without long-term adverse consequences if the source of the exposure is recognized and abated. Failure to recognize the disease early may lead to chronic irreversible lung changes with persistent symptoms in the patient.

ETIOLOGY

The most common sources of offending agents that cause HP include agricultural aerosols, inhaled protein antigens from animals, antigens from microorganisms of bacteria, fungi, or protozoan origin, as well as chemicals of low and high molecular weight (Table 399-1). Although a large number of inciting agents are associated with *occupational diseases* in which children do not regularly work, there are many similar antigen sources in a nonoccupational environment and teenage work exposures that may occur causing the same disease. In addition to HP, the same antigens may lead to allergic asthma or chronic bronchitis as seen with animal proteins, contaminated metal working fluids, and other inhaled antigens.

Primary sources of HP in children have been the result of exposure to **pet birds** (or feathers in bedding) such as parakeets, canaries, cockatiels, or cockatoos or homes contaminated with pigeon antigens from home breeders or contamination. Humidifiers and hot tubs are notorious for contamination with **thermophilic organisms** as well as *Mycobacterium avium* complex. Mold from prior flooding or damp condensation represents an increasing problem experienced by clinicians since the building of homes with inadequate ventilation and insufficient air turnover. Allergic diseases such as asthma, chronic rhinitis, and HP may be seen from the same sources. Other family members may have symptoms of asthma or rhinitis while another may have HP.

CLASSIFICATION AND PATHOGENESIS

HP has been traditionally classified as acute, subacute, or chronic. This classification arose prior to more refined diagnostic modalities such as **high-resolution computerized tomography (HRCT)** scanning of the lungs and more refined immunologic diagnostic tests on **bronchoalveolar lavage (BAL)**. Distinguishing chronic disease from subacute disease is difficult without clear differentiating criteria, but a diagnosis of HP at any stage results in the clinician recommending very specific interventions for improvement. HP is characterized as (1) acute nonprogressive and intermittent, (2) acute progressive and intermittent, (3) chronic nonprogressive, and (4) chronic progressive (Table 399-2).

The sensitivity of the complete criteria is lower than desired as not all patients will have abnormal radiography or the findings of positive precipitins to the offending antigen. The specificity of the criteria may also be problematic. Screening for pigeon breeder's lung disease among a cohort of pigeon breeders will demonstrate that 30% or more of the pigeon breeders have immunoglobulin (Ig) G precipitins to pigeon dropping antigens while only a small number will have disease. Genetic and epigenetic factors yet to be identified are likely involved in determining who develops disease.

A diagnosis of HP is certain when the known exposure with immune response to the offending antigen is identified; the medical history and physical finding are abnormal on examination; BAL and lung biopsy are abnormal. Some clinicians have foregone the lung biopsy when a cluster of cases occurs and 1 patient biopsy is abnormal already.

The immune mechanisms involved include morphologic changes seen with immune complex-mediated disease, especially in the acute phase, accompanied complement activation followed by delayed-type hypersensitivity response. The acute phase of the disease shows alveolitis with a mixed cellular infiltration with lymphocytes, macrophage, plasma cells, and neutrophils. Continued exposure results in the formation of loose, noncaseating granuloma located near the respiratory or terminal bronchioles. It is critical when a biopsy is being performed (transbronchial or surgical) that the pathologist knows that HP is being considered as there are other **interstitial lung diseases** that produce

Table 399-1 Antigen Sources Associated with Specific Causes of Hypersensitivity Pneumonitis

HYPERSENSITIVITY PNEUMONITIS	ANTIGEN SOURCE
Bagassosis (mold on pressed sugar cane)	*Thermoactinomyces sacchari* *Thermoactinomyces vulgaris*
Bat lung (bat droppings)	Bat serum protein
Bible printer's lung	Moldy typesetting water
Bird fancier's lung (parakeets, budgerigars, pigeons)	Droppings, feathers, serum proteins
Byssinosis ("brown lung") (unclear if a true cause of hypersensitivity pneumonitis; asthma is common)	Cotton mill dust (carding and spinning areas of cotton, flax, and soft-hemp)
Canary fancier's lung	Serum proteins
Cheese washer's lung (moldy cheese)	*Penicillium casei* *Aspergillus clavatus*
Chemical hypersensitivity pneumonitis	Diphenylmethane diisocyanate (MDI) Toluene diisocyanate (TDI)
Coffee worker's lung	Coffee-bean dust
Composter's lung	*T. vulgaris* *Aspergillus* species
Contaminated basement (sewage) pneumonitis	*Cephalosporium*
Coptic lung (mummy handler's lung)	Cloth wrappings of mummies
Detergent worker's lung (washing powder lung)	*Bacillus subtilis* enzymes
Dry rot lung	*Merulius lacrymans*
Duck fever	Feathers, serum proteins
Epoxy resin lung	Phthalic anhydride (heated epoxy resin)
Esparto dust (mold in plaster dust)	*Aspergillus fumigatus* Thermophilic actinomycetes
Fish meal worker's lung	Fish meal
Furrier's lung (sewing furs; animal fur dust)	Animal pelts
Grain measurer's lung	Cereal grain (*Sporobolomyces*) Grain dust (mixture of dust, silica, fungi, insects, and mites)
Hot-tub lung (mists; mold on ceiling and around tub)	*Cladosporium* spp. *Mycobacterium avium* complex
Humidifier fever	*Thermoactinomyces (T. vulgaris, T. sacchari, T. candidus)* *Klebsiella oxytoca* *Naegleria gruberi* *Acanthamoeba polyphaga* *Acanthamoeba castellani*
Laboratory worker's lung (rats, gerbils)	Urine, serum, pelts, proteins
Lifeguard lung	Aerosolized endotoxin from pool-water sprays and fountains
Lycoperdonosis (*Lycoperdon* puffballs)	Puffball spores
Machine operator's lung	*Pseudomonas fluorescens* Aerosolized metal working fluid
Malt worker's disease (moldy barley)	*Aspergillus fumigatus, Aspergillus clavatus*
Maple bark disease (moldy maple bark)	*Cryptostroma corticale*
Miller's lung (dust-contaminated grain)	*Sitophilus granarius* (i.e., wheat weevil)
Moldy hay, grain, silage (farmer's lung)	Thermophilic actinomycetes Fungi (e.g., *Aspergillus umbrosus*)
Mollusk shell hypersensitivity pneumonitis	Sea-snail shell
Mushroom worker's lung	Mushroom spores Thermophilic actinomycetes
Paprika slicer's lung (moldy paprika pods)	*Mucor stolonifer*
Pauli's reagent alveolitis	Sodium diazobenzene sulfate
Pearl oyster shell pneumonitis	Oyster shells
Pituitary snuff taker's disease	Dried, powdered cattle or pig pituitary proteins)
Potato riddler's lung (moldy hay around potatoes)	Thermophilic actinomycetes *T. vulgaris* *Faenia rectivirgula* *Aspergillus* spp.
Poultry worker's lung (feather plucker's disease)	Serum proteins (chicken products)
Pyrethrum (pesticide)	Pyrethrum
Sauna taker's lung	*Aureobasidium* spp., other sources
Sequoiosis (moldy wood dust)	*Graphium* *Pullularia* *Trichoderma* spp. *Aureobasidium pullulans*
Suberosis (moldy cork dust)	*Thermoactinomyces viridis* *Penicillium glabrum* Aspergillus conidia
Summer-type pneumonitis	*Trichosporon cutaneum*
Tea grower's lung	Tea plants
Thatched-roof lung (huts in New Guinea)	*Saccharomonospora viridis* (dead grasses and leaves)
Tobacco grower's lung	*Aspergillus* spp. *Scopulariopsis brevicaulis*
Turkey handling disease	Serum proteins (turkey products)
Unventilated shower	*Epicoccum nigrum*
Upholstery fabric (nylon filament, cotton/polyester, and latex adhesive)	Aflatoxin-producing fungus, *Fusarium* spp.
Velvet worker's lung	Unknown (? nylon velvet fiber, tannic acid, potato starch)
Vineyard sprayer's lung	Copper sulfate (bordeaux mixture)
Wine maker's lung (mold on grapes)	*Botrytis cinerea*
Wood dust pneumonitis (oak, cedar, and mahogany dust, pine and spruce pulp)	*Alternaria* spp. *Bacillus subtilis*
Wood pulp worker's disease (oak and maple trees)	*Penicillium* spp.
Wood trimmer's disease (contaminated wood trimmings)	*Rhizopus* spp., *Mucor* spp.

Table 399-2 Criteria Used in the Diagnosis of Hypersensitivity Pneumonitis

1. Identified exposure to offending antigen(s) by:
   - Medical history of exposure to suspected antigen in the patient's living environment
   - Investigations of the environment confirm the presence of an inciting antigen
   - Identification of specific immune responses (immunoglobulin G serum precipitin antibodies against the identified antigen) are suggestive of the potential etiology but are insufficient in isolation to confirm a diagnosis
2. Clinical, radiographic, or physiologic findings compatible with hypersensitivity pneumonitis:
   - Respiratory and often constitutional signs and symptoms
     - Crackles on auscultation of the chest
     - Weight loss
     - Cough
     - Breathlessness
     - Episodic fever
     - Wheezing
     - Fatigue

   NOTE: These findings are especially suggestive of hypersensitivity pneumonitis when they appear or worsen several hours after antigen exposure.
   - A reticular, nodular, or ground glass opacities on chest radiograph or high-resolution CT
   - Abnormalities in the following pulmonary function tests
     - Spirometry (restrictive, obstructive, or mixed patterns)
     - Lung volumes (low or high)
     - Reduced diffusion capacity by carbon monoxide
     - Altered gas exchange either at rest or with exercise (reduced partial pressure of arterial oxygen by blood gas or pulse oximeter testing)
3. Bronchoalveolar lavage with lymphocytosis:
   - Usually with low CD4:CD8 ratio (i.e., CD8 is higher than normal)
   - Lymphocyte stimulation by offending antigen results in proliferation and cytokine production
4. Abnormal response to inhalation challenge testing to the offending antigen:
   - Reexposure to the environment
   - Inhalation challenge to the suspected antigen (rarely done any longer because of the risk of exacerbation of the disease)
5. Histopathology showing compatible changes with hypersensitivity pneumonitis by 1 of these findings:
   - Poorly formed, noncaseating granulomas (most often found closer to the respiratory epithelium where deposition of the offending antigen occurs)
   - Mononuclear cell infiltrate in the pulmonary interstitium

similar granulomas with subtle location differences depending on their origin.

CLINICAL MANIFESTATIONS

Heavy exposure to an offending antigen may lead to **acute HP**. This is the most common form of exposure but is still frequently not recognized. Symptoms are confused with bacterial or viral disease leading to treatment with antibiotics. Four to 6 hr after exposure the abrupt onset of cough, chest tightness, dyspnea, fever, chills, and fatigue are common (Table 399-3) Rarely, findings of wheezing are present on the initial examination. Rather, tachypnea with fine crackles may be heard by auscultation in the lung bases. However, auscultation may be normal at this stage. When **recurrent subacute disease** is present, the symptoms become progressive with weight loss, loss of appetite, and productive cough. When HP becomes **chronic** and progressive, the patient's fingers become clubbed accompanied by persistent symptoms noted above denoting a deteriorating status. If the disease progresses to interstitial fibrosis, the symptoms tend to not respond to therapy and denote a state where mortality risk is increased. Histology is hard to distinguish from **idiopathic pulmonary fibrosis** at this stage.

Table 399-3 Clinical History Clues Leading to a Diagnosis of Hypersensitivity Pneumonitis

Recurrent pneumonia
Pneumonia after repeat exposures (week, season, situation)
Cough, fever, and chest symptoms after making a job change or home change
Cough, fever, wheezing after return to school or only at school
Pet exposure (especially birds that shed dust such as pigeons, canaries, cockatiels, cockatoos)
Bird contaminant exposure (e.g., pigeon infestation)
Farm exposure to birds and hay
History of water damage despite typical cleaning
Use of hot tub, sauna, swimming pool
Other family members or workers with similar recurrent symptoms
Improvement after temporary environment change (e.g., vacation)

LABORATORY

Most of the abnormal laboratory findings in hypersensitivity pneumonitis are not specific and represent evidence of activated inflammatory markers or lung injury. Nonspecific elevation of immune globulins or the erythrocyte sedimentation rate and C-reactive protein may also be found. Circulating immune complexes may be detected. Lactate dehydrogenase may be elevated in the presence of lung inflammation and normalizes with response to therapy.

Serum IgG precipitins to the offending agent are frequently positive given some caveats. Commercial antigen sources from animals and birds may contain insufficient antigen for precipitation. Some laboratories performing these tests on an infrequent basis often have false-negative tests presumed to be a result of commercial antigens lacking the proper epitopes for precipitation. It is critical that laboratories familiar with the performance of these tests be utilized. Those laboratories often recognize the value of processing antigens for precipitation from the environmental source directly as the test substrate with patient serum. Skin testing for IgE-mediated disease is not warranted unless there is evidence of mixed lung pathology such as asthma and interstitial lung opacities.

BAL is one of the most sensitive tests and very helpful to the clinician in supporting the diagnosis of HP. Lymphocytosis frequently exceeding 50% of the recovered cells is seen on the BAL and should alert the clinician to the possibility of HP. Sarcoid, idiopathic pulmonary fibrosis, cryptogenic organizing pneumonia, berylliosis, granite workers lung disease, amiodarone pneumonia, lymphoma, and Langerhans cell histiocytosis may demonstrate lymphocytosis on BAL. All BAL specimens should have flow cytometry measurements of T-cell markers (CD3, CD4, and CD8 at a minimum). The predominant phenotype of the lymphocytosis is CD3+/CD8+/CD56+/CD57+/CD10–. In the normal circulation, lymphocytes with CD4 markers predominate at a ratio of approximately 2 : 1 compared to CD8 lymphocytes. In the lung compartment with HP, this ratio becomes approximately equal to or less than 1 (CD4:CD8 ≤1) with either an increase in CD8 lymphocytes or a decline in CD4 lymphocytes. This ratio assists the clinician in making a diagnosis of HP. This is in sharp contrast to other lymphocytic granulomatous disease, like sarcoidosis, where the CD4:CD8 is ≥2, or pulmonary fibrosis associated with connective tissue disease. Cryptogenic organizing pneumonia, a rare disease in children, also may present with BAL, where the CD4:CD8 is ≤1, and may be confused initially with HP.

Lung Biopsy

Lung biopsy is necessary to confirm a diagnosis of HP when the presence of critical elements, like antigen exposure, typical medical history, characteristic physical exam, and CD8+ cells in the BAL, are not present. Open lung biopsy is often the route of choice in young children because of the difficulty in safely obtaining satisfactory amounts of tissue by transbronchial biopsy. Lack of positive serum precipitins to offending antigen and exposure history are common reasons for obtaining lung biopsies. It is crucial to inform the

pathologist about the suspicion of HP so that the findings can be interpreted appropriately.

Poorly formed, noncaseating granulomas are seen near the respiratory and terminal bronchioles on histology with multinucleated giant cells. This is in sharp contrast to the granuloma of sarcoidosis that are well formed. Lymphocytes and plasma cells infiltrate the alveolar walls predominantly in a bronchocentric pattern. Fibrosis in the peribronchiole region supports a diagnosis of HP. Foamy cytoplasm accompanying large histiocytes in the alveoli and interstitium may be characteristically found.

Radiology

Chest radiograph almost always precedes the use of HRCT of the chest in children because of the need for sedation and concerns regarding risk of irradiation dose from HRCT. The plain radiograph will often demonstrate a ground-glass appearance, interstitial prominence, with a predominant location in the upper and middle lung fields. It is common for a chest radiograph to be considered normal by a radiologist early in the disease progression. Late in the disease, interstitial fibrosis may become prominent in the presence of increasing dyspnea, hypoxemia on room air, and even clubbing of the fingers. Mediastinum widening from lymphadenopathy is not usually present; when present, the lymph nodes are prominent along the airway near the carina, suggesting that the antigen source is inhaled and being responded to by the immune system.

Classical findings of mid zone and upper zone opacities with ground-glass appearance and nodularity on HRCT in the presence of typical clinical exam HP findings (lung crackles, cough, dyspnea) and lymphocytosis on BAL are almost sufficient to make a diagnosis (Fig. 399-1). These finding must prompt the clinician to identify the exposure in order to secure the diagnosis and eliminate the offending antigen. Without therapy, the progressive inflammatory response leads to air trapping, honeycombing, emphysema, and mild fibrosis in the chronic state. It is in this latter stage that idiopathic pulmonary fibrosis and nonspecific interstitial fibrosis are hard to differentiate. Whether true idiopathic pulmonary fibrosis exists in children where fibroblast foci are found on biopsy with usual interstitial fibrosis has been questioned.

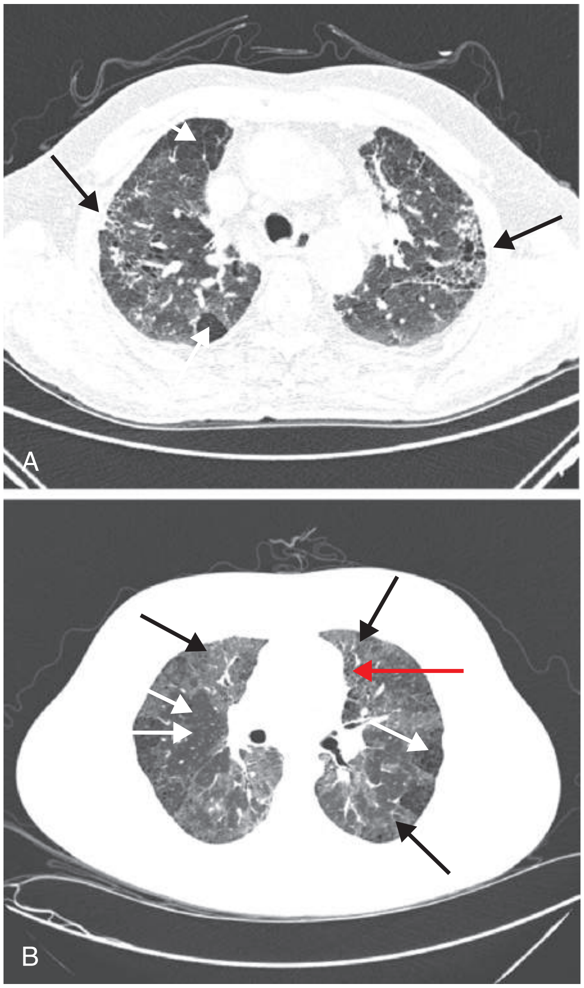

Figure 399-1 Radiologic findings in subacute **(A)** and chronic **(B)** hypersensitivity pneumonitis. **A,** Interstitial fibrosis *(black arrows)* and emphysematous changes *(white arrows)* in chronic HP with superimposed subacute HP. **B,** Ground-glass opacities *(black arrows)*, mosaic perfusion *(white arrows)*, and fibrosis *(red arrow)* in chronic HP caused by pigeon exposure. *(From Douglass JA, Sandrini A, Holgate ST, O'Hehir RE. Allergic bronchopulmonary aspergillosis and hypersensitivity pneumonitis. In Adkinson AF, editor:* Middleton's allergy principles and practice*, Philadelphia, 2014, Elsevier, Fig. 61-5.)*

Antigen Challenge By Inhalation

Inhalation challenge can be performed by 2 methods: (1) reexposure of the patient to the environment where the suspected antigen is present and (2) direct inhalation challenge at the hospital to material collected from the suspected source of the antigen. As the second method has resulted in severe exacerbation of disease in some individuals, its use is discouraged (see Chapter 399.2).

Two abnormal responses may be seen. Most commonly, where there is HP without asthma, symptoms occur 6-12 hr after direct challenge in the hospital or reexposure at source of the antigen. The challenges replicate some or all of the symptoms observed in the presenting syndrome with fever, dyspnea, fatigue, and crackles on lung auscultation. Blood drawn prior to challenge and then repeated during these symptoms often demonstrate an increased neutrophil count compared to baseline. Pulmonary function tests demonstrate a fall in **forced vital capacity** and often a concurrent fall in the **forced expiratory volume at 1 sec (FEV_1)** with a stable or increasing ratio of FEV_1:forced vital capacity percentage. Hypoxemia may accompany this decline in pulmonary function as well as a fall in the **diffusion capacity of carbon monoxide (DLCO).** To see the complete effect, exercise during this period may show a considerable fall in oxygenation despite normal arterial blood gas oxygen tension and normal pulse oximetry at rest. This finding denotes the onset of worsening restrictive lung disease. Some patients may also demonstrate an early and late reduction in the FEV_1 as is seen in allergen challenge with asthma. In this dual reaction, the forced vital capacity also declines and is often accompanied by fever and leukocytosis.

TREATMENT

The control of environmental exposure to the offending antigen is a key to curing HP and remains the ideal method of treatment and prevention of recurrence. Counseling about the risk to children of exposure to birds and feathered bedding, or other environmental antigens, biologic aerosols, or agriculture dusts that are known to induce HP are important. Certainly, the source of the antigen and type of antigen appears to affect response to treatment and long-term prognosis. Older individuals who contract farmer's lung are likely to recover with minimal permanent residual effect, whereas individuals with bird fancier's lungs from antigens produced by pigeons have a worse prognosis, especially if fibrosis is detected on lung biopsy. The pediatrician should advise—in the strongest terms—removal of the antigen source from the affected child's environment. This may be an extraordinary challenge given various children's living circumstances and lack of independent control of the environment they live in.

In addition, pediatricians should be familiar with recommendations about the maintenance of heating, ventilation, and air conditioning systems, as well as of humidifiers and vaporizers. Daily drainage, cleansing of residue, and routine cleaning with hydrogen peroxide or bleach help rid humidifiers and vaporizers of harmful pathogens that cause HP.

Glucocorticosteroids at a dose of 0.5-1 mg/kg/day of prednisone or equivalent will reduce the immune inflammatory response in the

lungs. Comparative trials in adults demonstrate that the use of 4 wks of therapy is as effective as 12 wks of therapy. Removal of antigen alone is sufficient to normalize lung function in most patients, but symptoms and pulmonary functions return to normal faster with the use of glucocorticoids. Because of the rapid reversal of symptoms, successful abatement of the environment is sometimes compromised when the family sees improvement prior to the antigen source removal.

399.2 Occupational and Environmental Lung Disease

Kevin J. Kelly

Occupational and environmental lung diseases constitute a larger part of primary care pediatrics, pediatric emergency medicine, and other pediatric subspecialties than most pediatric practitioners expect or realize. Although occupational and environmental lung diseases includes **occupational asthma**, **reactive airways dysfunction syndrome (RADS)**, HP, hard metal inhalation lung disease, berylliosis, and air pollution, this chapter focuses on occupational asthma and RADS. Berylliosis has a propensity to form granulomas (see Chapter 399.3). Although some diseases will be seen with regularity, the important role that a part-time workplace, school, daycare, neighbors' housing, multiple family housing, and indoor and outdoor environments may have in the causation of signs and symptoms in the patient is not always considered by the clinician.

The vast array of exposures shown to cause disease of the lungs is daunting, such as the inhalation of baking flour or household cleaning fluids causing asthma, microwave popcorn exposure to diacetyl resulting in bronchiolitis obliterans, and exposure to thermophilic organisms or mold resulting in hypersensitivity pneumonitis. The acute eosinophilic pneumonias associated with new onset of smoking and chemical inhalation of 1,1,1-trichloroethane (Scotchgard) require a high index of suspicion and unique lines of questioning. The same antigen encountered in a work, school, home, or outdoor environment may result in different disease presentation because of host factors, dose exposure, and genetic susceptibility. One of the most prominent examples is an investigation of workers who inhaled metal working fluid resulting in the development of asthma, HP, chronic bronchitis, or no symptoms at all from similar exposures. Immunologic evaluation in some exposures has shown similar immune responses in different individuals, but a wide range of disease provocation. When **high molecular weight** proteins cause asthma, symptoms of rhinoconjunctivitis frequently precede the onset of pulmonary symptoms. The medical history in occupational and environmental lung diseases has used an expanded construct with a simple acronym, WHACOS (Table 399-4).

Table 399-4	A Construct (WHACOS) That Has Been Used in Medical Interviewing of Patients, Coworkers, and Family Members When Environmental or Occupational Lung Disease Is Being Considered
W	*What* do you do?
H	*How* do you do what you do?
A	Are symptoms *Acute* or are they *Chronic*?
C	Do any *Coworkers*, family, classmates, or friends have the same symptoms?
O	Do you have any hobbies, travel, or animal/pet exposures *Outside* of school or work?
S	Are you *Satisfied* with work or school?

It is important to remember that in patients with occupational- or environmental-induced disease, the onset of symptoms has a lag time between exposure and symptoms. In occupational asthma, there may be an immediate response within 1-2 hr of exposure, demonstrated as a decline in pulmonary function, specifically the **FEV$_1$**. Usually, lung function returns to normal spontaneously unless persistent exposure occurs. Some patients demonstrate no immediate reduction in lung function, but rather experience a delayed response of 4-6 hr after the exposure. Treating physicians can take advantage of this physiology in occupational and environmental asthma by use of spirometry before and after work or school or peak flow measurements hourly during exposure and after leaving the exposure. Because workers and children in school have prolonged periods of exposure followed by a number of days without exposure, the use of pulmonary function plus bronchial hyperresponsiveness testing is helpful. Pulmonary function tests prior to starting work on a Monday of a typical work week may be normal. By Friday of a typical work or school week, the baseline pulmonary functions may have fallen and bronchial responsiveness may have become more sensitive to a lower concentration of histamine, methacholine, or mannitol. By Monday, the tests may have returned to normal or near normal with no change other than reduced exposure.

In the case of HP, a lag of 4-8 hr between the time of exposure and onset of fever, cough, and dyspnea is common. Unfortunately, the return home from hospitalization for culture-negative pneumonia to a source of antigen causing HP often results in complete reoccurrence of symptoms. Clinicians must have a high index of suspicion for HP with reoccurrence of pulmonary infiltrates shortly after reexposure (see Chapter 399.1).

CLASSIFICATION AND PATHOGENESIS

Occupational and environmental lung diseases include numerous syndromes of human lung disease such as occupational asthma, **RADS**, **reactive upper airway disease syndrome**, hypersensitivity pneumonitis (see Chapter 399.1), air pollution–induced disease, hard metal inhalation lung disease, berylliosis, occupation-induced lung cancer (e.g., mesothelioma from asbestosis), and chronic obstructive pulmonary disease without smoking. Most of these diseases are not problematic for children but adolescents may be exposed through part-time work or by single exposures as seen in RADS.

Occupational and Environmental Asthma

The general principles of diagnosis, clinical signs and symptoms, treatment, and causes of asthma are discussed in Chapter 144. High molecular weight causes of occupational and environmental asthma can be characterized as allergens, which are normally proteins and enzymes, inhaled from multiple sources (Table 399-5). These include various animals, shellfish, fish, enzymes (e.g., *Bacillus subtilis* in laundry detergent), and flour or cereals. Occupational and environmental asthma is also caused by a number of low molecular weight chemicals (Table 399-6). These chemicals are sufficient to induce an immune response but it is often not by an IgE-mediated mechanism. These chemicals appear to act as haptens that bind to human proteins, causing an immune response in the human host.

The pathogenesis of asthma in patients exposed to high molecular weight antigens follows the experience of nonoccupational asthma in patients where atopy, gender, genetics, concentration of antigen, duration of exposure, and other individual factors all contribute to the development of disease. Most individuals require a concentration and duration of exposure sufficient to cause IgE antibody sensitization to the offending allergen with development of bronchial hyperresponsiveness and airway inflammatory disease. If the allergen exposure is sufficient, these proteins can drive the immune response to a T-lymphocyte type 2 phenotype, even in patients without prior atopic disposition, as occurred in the case of latex allergy where many nonatopic individuals and patients exposed to allergen in their personal healthcare developed occupational allergy to multiple proteins from natural rubber latex. Atopic individuals are at the highest risk of developing latex allergy. A longitudinal study demonstrated that powdered latex gloves with high allergen content were the reason for the epidemic of latex allergy and

Table 399-5 High Molecular Weight Antigens Known to Induce Occupational or Environmental Asthma

OCCUPATION OR ENVIRONMENT	SOURCE
ANIMAL-DERIVED ANTIGENS	
Agricultural worker	Cow dander
Bakery	Lactalbumin
Butcher	Cow bone dust, pig, goat dander
Cook	Raw beef
Dairy industry	Lactoserum, lactalbumin
Egg producer	Egg protein
Farmer	Deer dander, mink urine
Frog catcher	Frog
Hairdresser	Sericin
Ivory worker	Ivory dust
Laboratory technician	Bovine serum albumin, laboratory animal, monkey dander
Nacre buttons	Nacre dust
Pharmacist	Endocrine glands
Pork producer	Pig gut (vapor from soaking water)
Poultry worker	Chicken
Tanner	Casein (cow's milk)
Various	Bat guano
Veterinarian	Goat dander
Zookeeper	Birds
CRUSTACEANS, SEAFOOD, FISH	
Canning factory	Octopus
Diet product	Shark cartilage
Fish food factory	Gammarus shrimp
Fish processor	Clam, shrimp, crab, prawn, salmon, trout, lobster, turbot, various fishes
Fisherman	Red soft coral, cuttlefish
Jewelry polisher	Cuttlefish bone
Laboratory grinder	Marine sponge
Oyster farm	Hoya (oyster farm prawn or sea-squirt)
Restaurant seafood handler	Scallop and shrimp
Scallop plant processor	King scallop and queen scallop
Technician	Shrimp meal *(Artemia salina)*
ARTHROPODS	
Agronomist	*Bruchus lentis*
Bottling	Ground bug
Chicken breeder	Herring worm *(Anisakis simplex)*
Engineer at electric power plant	Caddis flies *(Phryganeidae)*
Entomologist	Lesser mealworm (*Alphitobius diaperinus* Panzer), moth, butterfly
Farmer	Grain pests (*Eurygaster* and *Pyrale*)
Fish bait handler	Insect larvae *(Galleria mellonella)*, mealworm larvae *(Tenebrio molitor)*, green bottle fly larvae *(Lucila caesar)*, daphnia, fish-feed Echinodorus larva *(Echinodorus plasmosus)*, Chiromids midge *(Chironomus thummi thummi)*
Fish processing	Herring worm *(Anisakis simplex)*
Flight crew	Screw worm fly *(Cochliomyia hominivorax)*
Honey processors	Honeybee
Laboratory worker	Cricket, fruit fly, grasshopper *(Locusta migratoria)*, locust
Mechanic in a rye plant	Confused flour beetle *(Tribolium confusum)*
Museum curator	Beetles (Coleoptera)
Seed house	Mexican bean weevil *(Zabrotes subfasciatus)*
Sericulture	Silkworm, larva of silkworm
Sewage plant worker	Sewer fly *(Psychoda alternata)*
Technician	Arthropods *(Chrysoperla carnea, Leptinotarsa decemlineata, Ostrinia nubilalis, and Ephestia kuehniella)*, sheep blowfly *(Lucilia cuprina)*
Wool worker	*Dermestidae* spp.
ACARIANS	
Apple grower	Fruit tree red spider mite *(Panonychus ulmi)*
Citrus farmer	Citrus red mite *(Panonychus citri)*
Farmer	Barn mite, two-spotted spider mite *(Tetranychus urticae)*, grain mite
Flour handler	Mites and parasites
Grain-store worker	Grain mite
Horticulturist	*Amblyseius cucumeris*
Poultry worker	Fowl mite
Vine grower	McDaniel spider mite *(Tetranychus mcdanieli)*
MOLDS	
Agriculture	*Plasmopara viticola*
Baker	*Alternaria, Aspergillus* (unspecified)
Beet sugar worker	*Aspergillus* (unspecified)
Coal miner	*Rhizopus nigricans*
Coffee maker	*Chrysonilia sitophila*
Laborer	Sooty molds (*Ascomycetes*, deuteromycetes)
Logging worker	*Chrysonilia sitophila*
Plywood factory worker	*Neurospora*
Sausage processing	*Penicillium nalgiovense*
Sawmill worker	*Trichoderma koningii*
Stucco worker	*Mucor* spp. (contaminating esparto fibers)
Technician	*Dictyostelium discoideum* (mold), *Aspergillus niger*
MUSHROOMS	
Agriculture	*Agaricus bisporus* (white mushroom)
Baker	Baker's yeast *(Saccharomyces cerevisiae), Boletus edulis*
Greenhouse worker	Sweet pea *(Lathyrus odoratus)*
Hotel manager	*Boletus edulis*
Mushroom producer	*Pleurotus cornucopiae*
Mushroom soup processor	Mushroom unspecified
Office worker	*Boletus edulis*
Seller	*Pleurotus ostreatus* (spores of white spongy rot)
ALGAE	
Pharmacist	Chlorella
Thalassotherapist	Algae (species unspecified)
FLOURS	
Animal fodder	Marigold flour *(Tagetes erecta)*
Baker	Wheat, rye, soya, and buckwheat flour; Konjac flour; white pea flour *(Lathyrus sativus)*
Food processing	White Lupin flour *(Lupinus albus)*
POLLENS	
Florist	Cyclamen, rose
Gardener	Canary island date palm *(Phoenix canariensis)*, Bell of Ireland *(Moluccella laevis)*, Bell pepper, chrysanthemum, eggplant *(Solanum melongena)*, *Brassica oleracea* (cauliflower and broccoli)
Laboratory worker	Sunflower (*Helianthus* spp.), thale cress *(Arabidopsis thaliana)*
Olive farmers	White mustard *(Sinapis alba)*
Processing worker	*Helianthus annuus*

Table 399-5 High Molecular Weight Antigens Known to Induce Occupational or Environmental Asthma—cont'd

OCCUPATION OR ENVIRONMENT	SOURCE
PLANTS	
Brewery chemist	Hops
Brush-makers	Tampico fiber in agave leaves
Butcher	Aromatic herb
Chemist	Linseed oilcake, *Voacanga africana* seed dust
Cosmetics	Dusts from seeds of Sacha Inchi *(Plukenetia volubilis)*, chamomile (unspecified)
Decorator	Cacoon seed (Entage gigas)
Floral worker	Decorative flower, safflower *(Carthamus tinctorius)* and yarrow *(Achillea millefolium)*, spathe flower, statice *(Limonium tataricum)*, baby's breath *(Gypsophila paniculata)*, ivy *(Hedera helix)*, flower (various), sea lavender *(Limonium sinuatum)*
Food industry	Aniseed, fenugreek, peach, garlic dust, asparagus, coffee bean, sesame seed, grain dust, carrot *(Daucus carota L.)*, green bean *(Phaseolus multiflorus)*, lima bean *(Phaseolus lunatus)*, onion, potato, swiss chard *(Beta vulgaris L.)*, courgette, carob bean, spinach powder, cauliflower, cabbage, chicory, fennel seed, onion seeds (*Allium cepa*, red onion), rice, saffron *(Crocus sativus)*, spices, grain dust
Gardener	Copperleaf *(Acalypha wilkesiana)*, grass juice, weeping fig *(Ficus benjamina)*, umbrella tree (*Schefflera* spp.), amaryllis (*Hippeastrum* spp.), Madagascar jasmine sap *(Stephanotis floribunda)*, vetch *(Vicia sativa)*
Hairdresser	Henna (unspecified)
Herbal tea processor	Herbal tea, sarsaparilla root, sanyak *(Dioscorea batatas)*, Korean ginseng *(Panax ginseng)*, tea plant dust *(Camellia sinensis)*, chamomile (unspecified)
Herbalist	Liquorice roots (*Glycyrrhiza* spp.), wonji *(Polygala tenuifolia)*, herb material
Horticulture	Freesia (Freesia hybrida), paprika *(Capsicum annuum)*, Brazil ginseng *(Pfaffia paniculata)*
Laborer	Citrus food handling (*dl*-limonene, *l*-citronellol, and dichlorophen)
Oil industry	Castor bean, olive oilcake
Pharmaceutical	Rose hip, passion flower *(Passiflora alata)*, cascara sagrada *(Rhamnus purshiana)*
Powder	Lycopodium powder
Sewer	Kapok
Sheller	Almond shell dust
Stucco handler	Esparto (*Stipa tenacissima* and *Lygeum spartum*)
Tobacco manufacturer	Tobacco leaf
PLANT-DERIVED NATURAL PRODUCTS	
Baker	Gluten, soybean lecithin
Candy maker	Pectin
Glove manufacturer	Latex
Health professional	Latex
Rose extraction	Rose oil
BIOLOGIC ENZYMES	
Baker	Fungal amylase, fungal amyloglucosidase and hemicellulase
Cheese producer	Various enzymes in rennet production (proteases, pepsine, chymosins)
Detergent industry	Esterase, *Bacillus subtilis*
Factory worker	*Bacillus subtilis*
Fruit processor	Pectinase and glucanase
Hospital personnel	Empynase (pronase B)
Laboratory worker	Xylanase, phytase from *Aspergillus niger*
Pharmaceutical	Bromelin, flaviastase, lactase, pancreatin, papain, pepsin, serratia peptidase, and lysozyme chloride; egg lysozyme, trypsin
Plastic	Trypsin
VEGETABLE GUMS	
Carpet manufacturing	Guar
Dental hygienist	*Gutta-percha*
Gum importer	Tragacanth
Hairdresser	Karaya
Printer	Acacia

Table 399-6 Low Molecular Weight Chemicals Known to Induce Occupational or Environmental Asthma

CHEMICALS	OCCUPATION OR ENVIRONMENT SOURCE
Diisocyanates	
• Diphenylmethane	Polyurethane
• Hexamethylene	Roofing materials
• Naphthalene	Insulations
• Toluene	Paint
Anhydrides • Trimellitic • Phthalic	Manufacturers or users • Paint • Plastics • Epoxy resins
Dyes • Anthraquinone • Carmine • Henna • Persulfate	Personal or business use of dyes • Hair dye • Fur dye • Fabric dye
Glue or resin • Methacrylate • Acrylates • Epoxy	Plastic • Manufacturers • Healthcare professionals • Orthopedic specialists
Metals • Chromic acid • Potassium dichromate • Nickel sulfate • Vanadium • Platinum salts	Metal work • Plating • Welding
Drugs • β-Lactams • Opioids • Other	Exposure to drugs in environment • Pharmaceutical workers • Farmers • Healthcare workers
Chemicals • Formaldehyde • Glutaraldehyde • Ethylene oxide	Exposure in the healthcare field • Laboratory work • Healthcare professionals
Wood dust • Western red cedar (plicatic acid) • Exotic woods • Maple • Oak	Workers/hobbyists • Sawmill • Carpentry • Woodworking

occupational asthma. Occupational asthma induced from multiple causes persists in individuals affected approximately 50% of the time despite primary removal of the sensitizing allergen.

Reactive Airways Disease Syndrome and Irritant-Induced Asthma

RADS presents with the development of acute respiratory symptoms within minutes or hours following a single inhalation of a *high concentration* of irritant gas, aerosol, or smoke. Table 399-7 lists the criteria for diagnosis of RADS. Asthma-like symptoms and airway hyperresponsiveness then ensue, which often persist for prolonged periods. Unlike typical asthma, RADS is often not reversible by use of a bronchodilator. This is probably a consequence of the direct injury to the epithelium and subsequent submucosal fibrosis. Chlorine gas, acetic acid, dimethylaminoethanol, chlorofluorocarbons, epichlorohydrin, and diisocyanates have been studied by experimental design of comparative groups or epidemiology studies.

Irritant induced asthma is a closely related form of asthma resulting from nonimmunologic provocation of bronchial hyperresponsiveness with airflow obstruction induced by irritant chemicals in *low concentration* after single or multiple exposures. If the resultant pulmonary symptoms occur after multiple exposures at a plant, it is termed *nonimmunologic-induced asthma*.

Predisposing factors for the development of RADS are not well characterized. Atopy and cigarette smoking may increase the risk of developing RADS when exposure through inhalation of irritant chemicals occurs. In addition to host factors, the type of chemical appears to be important. Higher concentrations of chemicals, the type of chemical (vapor or wet aerosols), and bleaching agents are the most offending agents to cause RADS. Dry particle aerosols are less likely to cause RADS. Analysis of the World Trade Center firefighters indicates that the presence of bronchial hyperresponsiveness prior to a chemical exposure does not increase the risk for an individual to develop RADS.

Pathogenesis of RADS follows a typical pattern. Initial histology demonstrates rapid denudation of the mucosa accompanied by submucosal fibrinous, hemorrhagic exudate. Subepithelial edema occurs subsequently with some regeneration of the epithelial layer, proliferation of basal and parabasal cells, and eventually areas of fibrosis. The desquamation, subepithelial fibrosis, thickening of the basement membrane, and regeneration of basal cells are all more prominent in RADS than in occupational asthma. This may explain the limited response to bronchodilator therapy in this syndrome compared to asthma.

The clinical manifestations of RADS and irritant-induced asthma are different from each other mostly in the onset of symptoms. Patients with RADS typically can pinpoint the exact time of onset of symptoms as well as the exact number of hours postexposure. The symptoms are so severe that nearly 80% of subjects in one study presented to an emergency department for care. The lower airway symptoms of cough, dyspnea, chest tightness, and wheezing are prominent features in RADS, with cough being most prevalent. Because of the toxic nature of the inhaled chemical, it is predictable that an upper airway syndrome of throat and nose burning will often accompany the lower airway symptoms. This part of the complex has been referred to as **respiratory upper airway dysfunction syndrome.**

Individuals with irritant-induced asthma present with a more insidious onset of symptoms. Because of the recurrent nature of the low concentration of chemical, patients may not be able to identify the underlying trigger initially. Similar to allergic rhinitis, patients may describe nasal congestion, rhinorrhea, sneezing, postnasal drip, ocular irritation, and conjunctival injection. Pulmonary symptoms include those typically seen with asthma exacerbations.

Initial evaluation of the patient with RADS or irritant-induced asthma usually includes the medical history, physical examination, and pulse oximetry. Because of the acute nature of RADS, a chest radiograph is obtained in order to rule out other acute causes of dyspnea including pneumonia or pulmonary edema. Ideally, if the patient is not in significant distress, complete pulmonary functions with spirometry, lung volumes, and diffusion capacity are very helpful in the initial evaluation. The lack of abnormality on initial chest radiograph reassures the clinician that HRCT is not indicated.

Table 399-7	Criteria for the Diagnosis of Reactive Airways Disease Syndrome
Absence of previous documented respiratory symptom	
Onset of symptoms most often occur after a single specific exposure	
Exposure is most often to a high concentration of gas, smoke, fume, or vapor with irritant qualities	
Symptoms occur within 24 hr of exposure and persist for 3 mo or longer	
Symptoms mimic asthma with cough, wheezing, shortness of breath, and/or dyspnea	
Pulmonary function tests may demonstrate airflow obstruction but not always	
Bronchial hyperresponsiveness is documented by methacholine challenge	
Alternative pulmonary diseases are not able to be found	

TREATMENT

Treatment of RADS and irritant-induced asthma focuses on prevention of exposure. Because the exposure in RADS is often associated with a single known exposure, this task is readily accomplished. The low, persistent exposures are more challenging to identify and remove. Implementing treatment guidelines for asthma from all causes is recommended when intervention is required beyond antigen removal.

Bibliography is available at Expert Consult.

399.3 Granulomatous Lung Disease

Kevin J. Kelly

GRANULOMATOSIS WITH POLYANGIITIS

Granulomatosis with polyangiitis (GPA) is a disease that involves both the lower and upper respiratory tracts with granulomatous inflammation of small vessels; formerly it was known as *Wegener granulomatosis* (see Chapter 167). The pulmonary disease is frequently associated with glomerulonephritis. The simultaneous presence of pulmonary and renal disease should immediately raise the suspicion that either GPA or Goodpasture disease (see Chapter 399.5) may be causing the disease.

Etiology and Epidemiology

The prevalence of GPA disease appears to be increasing by up to 4-fold in the last 2 decades, but without male or female predominance. Diagnostic tests, such as antineutrophil antibodies, may explain some of this increased prevalence.

Pathogenesis

Clinically, the development of both upper and lower airway disease with granulomas in GPA implies that exposure to antigen in the airway of endogenous or exogenous source is involved with aberrant cell-mediated immune response. Cytokine expression by peripheral blood CD4+ lymphocytes and cells collected by BAL indicate there is a predominantly T-lymphocyte type 1 response with overexpression of interferon-γ (IFN-γ) and tumor necrosis factor (TNF). In vitro studies demonstrate a skewed T-lymphocyte type 17 response by blood CD4+ T cells in GPA, suggesting there is an immune regulatory defect that leads to excessive production of T-lymphocyte type 1/T-lymphocyte type 17 cytokines (interleukin [IL]-17, TNF, and IFN-γ) presumed to be from the environment or autoantigens. Such an inflammatory response may be sufficient to induce and sustain granuloma formation.

Detection of *autoantibodies reactive against proteins in the cytoplasmic granules of neutrophils and monocytes (antineutrophil cytoplasmic antibodies [ANCAs])* are found in 90% of the patients with GPA. The first major type of ANCA is directed against cytoplasmic proteinase-3 and is frequently named c-ANCA. The second major type of ANCA recognizes the enzyme myeloperoxidase. It is found in a small number (<10%) of patients with GPA. Antimyeloperoxidase antibodies fluoresce in a perinuclear pattern and are often referred to as perinuclear ANCA. In contrast, some patients develop the clinical phenotype of GPA in the absence of detectable ANCA.

Clinical Manifestations

Children with GPA present with respiratory complaints accompanied by fever, loss of energy, and vague joint complaints. Some may present with severe nasal disease manifested as ulceration, septal perforation, pain, sinusitis, and or epistaxis. The septal perforation may lead to deformation of the nasal bridge from erosion of the underlying cartilage but is more common in adults. Pulmonary disease occurs in the majority of patients as noted above. Symptoms range from cough, hemoptysis, dyspnea, and chest discomfort to asymptomatic infiltrates on chest radiography. Occasionally, patients with GPA will present with hemoptysis or recurrent fleeting infiltrates from **pulmonary hemorrhage**. The pathology is confusing because granulomatous disease may be difficult to demonstrate and can be confused with microscopic polyangiitis. This is found most frequently in Goodpasture disease, microscopic polyangiitis, and Henoch-Schönlein purpura. Distinguishing GPA from other pulmonary renal syndromes is easiest when there are classical symptoms of upper airway disease (nasal/sinus), lower airway disease with necrosis, granulomas on biopsy of the lung with vasculitis, and renal disease consistent with glomerulonephritis.

As many as 20% of patients with GPA will present with subglottic or endobronchial stenosis from scarring and inflammatory changes. Although it may be the presenting symptom, it often occurs in conjunction with other disease manifestations. Dyspnea and voice changes are common complaints from the patients.

Skin, ocular, and joint symptoms are common in GPA and have been found to accompany the lung and renal disease in most series 50% or more of the time. Biopsy of the skin may show nonspecific leukocytoclastic vasculitis, venulitis, or capillaritis.

Laboratory and Pathology

c-ANCA or anti–proteinase-3 antibodies are found in 90% of patients with GPA. However, they are also found in other types of vasculitis and are not sufficient in themselves to make a diagnosis without a tissue biopsy (see Chapter 167). Because of the necrotizing nature of the vasculitis, lung tissue is required for definitive diagnosis of pulmonary disease. Biopsy of the upper airway may demonstrate evidence of granulomatous disease but it is uncommon to find evidence of vasculitis; lung biopsy is warranted. Usual pathology demonstrates multiple parenchymal nodules that may be located in either the bronchial, vascular, or interstitial tissues (Fig. 399-2). The granulomatous inflammation often is found areas of necrosis and/or vasculitis.

Renal biopsy rarely is able to demonstrate granulomas or vasculitis. Rather, kidney tissues may show focal, segmental, or necrotizing glomerulonephritis without deposits of immune complexes. When the tissues fail to demonstrate classical findings, a variety of diseases (e.g., tuberculosis, sarcoid, microscopic polyangiitis, malignancy, and other autoimmune disorders) must be considered in the evaluation.

Radiology

Chest radiography in GPA will show multiple infiltrates, nodules, cavitary lesions, or interstitial lung disease. Fleeting infiltrates may be seen when recurrent hemorrhage is a part of the clinical manifestation. HRCT often demonstrates more extensive lung disease and the cavitation associated with the necrotizing nature of the disease (Fig. 399-3).

Treatment

Rapidly progressive, debilitating disease may occur when failure to diagnose GPA leads to inadequate treatment. One series of patients showed death occured in 90% of patients within 2 yr of diagnosis. Glucocorticoid therapy alone resulted in relapses and inadequate control of disease in many subjects. Standard initial induction of therapy includes prednisone at 1 mg/kg/day in combination with oral cyclophosphamide at 2 mg/kg/day or intravenous dosing at 15 mg/kg

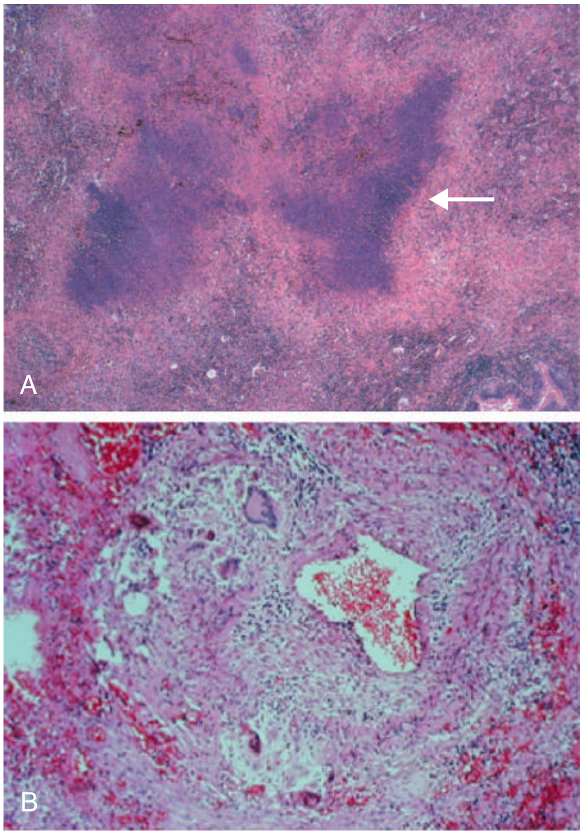

Figure 399-2 A, Low-power view of granulomatous inflammation and geographic necrosis (*arrow*) in a lung biopsy from a patient with GPA. **B,** Granulomatous vasculitis involving a small pulmonary artery in the lung of a patient with GPA. Figure 399-3 Chest CT scan of a patient with granulomatosis with polyangiitis shows typical nodular lung infiltrate with cavitation. *(From Sneller MC, Fontana JR, Shelhamer JH. Immunologic nonasthmatic diseases of the lung. In Adkinson AF, editor:* Middleton's allergy principles and practice, *Philadelphia, 2014, Elsevier, Fig. 61-1A.)*

monthly. This regimen is effective at induction of remission of disease process. The advantage of oral daily dosing is a reduction in relapse of disease once induction has occurred. After induction of remission (usually in 3 mo), prednisone can be tapered to an every-other-day regimen and eventually discontinued in 6-8 mo. After induction of remission, cyclophosphamide should be discontinued because of drug toxicity, serious risk of infections, risk of infertility, or cancer. In those patients with recurring relapse, cyclophosphamide has had limited use.

Once remission was achieved and cyclophosphamide discontinued; both methotrexate and azathioprine demonstrated efficacy with lowered side effects during maintenance of remission therapy for approximately 1 yr.

Adjuvant therapy with plasma exchange may be considered when life-threatening GPA disease presents. This is advocated on the premise that ANCAs are inducing disease and will be removed from the circulation with this intervention; its use has been favorably evaluated in GPA-induced renal disease. Plasmapheresis and exchange is advocated as adjuvant treatment for severe manifestations of GPA and related ANCA-associated disease based on the theoretical benefit of removing potentially pathogenic ANCA. Adjuvant plasma exchange has been studied mainly in patients with severe renal vasculitis, but there are also reports of success in severe pulmonary hemorrhage. The results of a meta-analysis of patients with renal vasculitis in 9 trials, suggest that adjuvant plasma exchange may be associated with improved renal outcome.

The removal of B-cells that produce ANCAs may be effective by reducing the production of pathogenic antibodies. Rituximab, an anti-CD20 chimeric antibody, regimens used in conjunction with glucocorticoids or glucocorticoids with a short course of cyclophosphamide are equally efficacious in inducing remission when compared to more prolonged therapy with steroid plus cyclophosphamide.

Recurrent disease remains a major problem. ANCA levels have not been shown to correlate with activity of disease or severity. Patients with isolated disease of the sinuses and nose may not warrant such toxic therapy. Therapy with topical corticosteroid and antibiotics for infection appear to be warranted. If unsuccessful, steroid with methotrexate appears to be an effective therapy.

The development of subglottic stenosis requires specific treatment. Use of cyclophosphamide with oral corticosteroid may have an incomplete or no response in the airway. Local injection of a prolonged acting corticosteroid locally appears to be indicated to reduce the inflammation and prevent further scarring. If this complication is found at presentation, simultaneous airway intervention with induction of corticosteroid and cyclophosphamide is warranted and encouraged.

SARCOIDOSIS

Sarcoidosis is an idiopathic inflammatory disease involving multiple organ systems, with characteristic histology of noncaseating granulomas (see Chapter 165). It has been postulated that sarcoidosis represents an immune response to a yet-to-be-identified agent from the environment that is likely inhaled in a susceptible host. It remains a diagnosis of exclusion from other diseases with granuloma formation on histology, such as immune deficiency of chronic granulomatous disease, granulomatous lymphocytic interstitial lung disease associated with common variable immune deficiency, HP associated with some drugs and inhalation agents, granuloma with polyangiitis, typical and atypical *Mycobacterium*, *Pneumocystis jiroveci*, and malignancy.

Epidemiology and Pathogenesis

African-American females are disproportionately affected more than any other group. Because an asymptomatic sarcoid-like distribution of noncaseating granulomas may be frequently found at autopsy, the contribution of the granulomas to the disease is not always clear. Some countries do mass chest radiograph screening for multiple diseases. In that setting, up to 50% of diagnosed sarcoidosis is asymptomatic. The severity of the disease appears to be worse in African-Americans who tend to have acute illness, whereas white subjects are more likely to be asymptomatic with a more chronic disease. There have been clusters of disease in families and genetic testing suggests that MHC linkage on the short arm of chromosome 6 is most likely to be observed.

Sarcoidosis is rarely found in children younger than the age of 8 yr; those of African descent are most affected. The disease presentation is similar to adults with multisystem disease being the most common. Skin rash, iridocyclitis, and arthritis are seen most often without pulmonary symptoms. In northern Europe, erythema nodosum with the ocular involvement of iridocyclitis is seen most frequently. Despite the lack of symptoms, chest radiography may be abnormal in approximately 90% of children. The pulmonary disease appears to be less progressive compared to adults and patients recover spontaneously without corticosteroids. Rarely, pulmonary disease may progress to fibrosis. Ocular disease is more likely to be progressive and warrant intervention as the inflammatory response may lead to blindness from complications of iritis.

Unrecognized infection or inhalation of an immune response–inducing antigen continues to be at the forefront of consideration as a cause of the disease. Clusters of sarcoidosis in small populations, variable prevalence by geography and race, transfer of disease by organ transplant, and the reproducible granuloma formation only in patients with sarcoidosis in the skin when homogenized lymph node tissue from patients with sarcoid are injected intradermally (Kveim-Siltzbach test) have supported this hypothesis.

Clinical Manifestations

Patients with lung disease are more likely to be asymptomatic as the presentation often may be an abnormal chest radiograph. When symptomatic, patients demonstrate shortness of breath, cough, and dyspnea. Children are more likely to manifest the disease as iridocyclitis, skin rash, and arthritis. African-American children appear to have more frequent lymph node involvement, nonspecific elevations of gamma globulin, erythema nodosum, and hypercalcemia. Physical exam may reveal only an elevated respiratory rate without crackles or rales by auscultation. Pleural involvement has been seen but is uncommon. When present, a lymphocytic predominant exudate may be observed with laboratory evaluation of the pleural fluid. Unusual but reported findings include cases of pneumothorax, hemothorax, and chylothorax. One specific syndrome, **Lofgren syndrome**, with hilar lymphadenopathy, erythema nodosum, and migratory polyarthralgias, is almost exclusively seen in women. This syndrome has a strong association with HLA-DQB1*0201 and polymorphisms in the C-C chemokine receptor 2 (CCR2); these genetic markers are a predictor of a good outcome.

Although almost 90% of patients with sarcoidosis demonstrate parenchymal or mediastinal disease on chest radiography, there are many who have minimal to no symptoms. Approximately 40% of adults with stage 1 disease have endobronchial involvement found at bronchoscopy. The higher the staging level of disease, the higher the percentage of people with airway involvement.

Diagnostic Laboratory Testing

The most common but nonspecific findings are hypergammaglobulinemia, hypercalciuria, hypercalcemia, elevated alkaline phosphatase when liver disease is present, and, occasionally, anemia of chronic disease. Serum angiotensin-converting enzyme may be elevated in 75% of patients with untreated sarcoid. False-positive tests occur from other diseases so that it is not considered a diagnostic test but rather a test that strongly supports the diagnosis.

Pulmonary function tests are able to be performed accurately in most children older than the age of 4 yr. There are no specific diagnostic findings of spirometry, lung volumes, or diffusion capacity in sarcoidosis. Exercise coupled with pulmonary function tests may demonstrate a decline in diffusion capacity when alveolitis is present in hypersensitivity pneumonitis and could add diagnostic help to the clinician when attempting to differentiate sarcoidosis from HP prior to biopsy.

BAL is of great help when differentiating HP from sarcoid. BAL in sarcoid shows a marked predominance of CD4 cells. A lymphocyte

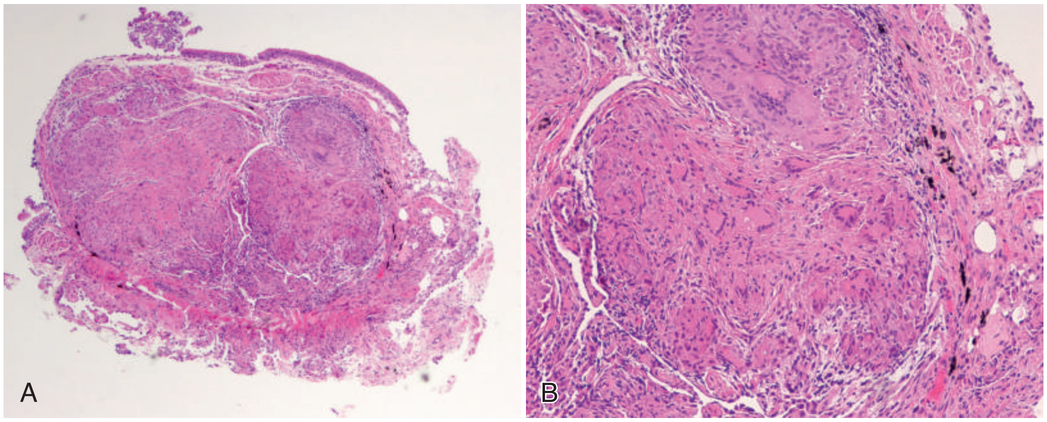

Figure 399-4 Transbronchial biopsy specimen showing a sarcoid granuloma. **A,** The granulomas are located below the bronchiolar epithelial layer that appears at the top of the frame. **B,** A higher-power view of the same biopsy specimen. The epithelioid granuloma is tightly packed and contains multiple multinucleated giant cells. There is no caseous necrosis. Special stains for acid-fast bacilli and fungi were negative. *(From Sneller MC, Fontana JR, Shelhamer JH. Immunologic nonasthmatic diseases of the lung. In Adkinson AF, editor:* Middleton's allergy principles and practice, *Philadelphia, 2014, Elsevier, Fig. 61-6.)*

percentage >16% on BAL, a CD4:CD8 ratio >4, and noncaseating granulomas on bronchial biopsy in the presence of abnormal angiotensin-converting enzyme levels are nearly completely diagnostic for sarcoid. In addition, T cells are activated on BAL. BAL in HP shows a significant change in the balance of CD4 to CD8 cells with the 2 cell types being nearly equal compared to the normal mild predominance of CD4 cells in the circulation. A ratio of CD4:CD8 of <1 predicts 100% of patients with BAL lymphocytosis to *not* have sarcoidosis. Neutrophil counts >2% and/or eosinophil counts >1% exclude the diagnosis of sarcoidosis.

The analysis of D-dimers in BAL fluid from subjects with sarcoidosis demonstrates an elevation in 80% of patients compared to no detectable D-dimers in unaffected control.

Histopathology

The characteristic feature of sarcoidosis is the noncaseating granuloma formation in the lung (Fig. 399-4). These granulomas are found in the bronchial walls, alveolar septa, and vascular walls of pulmonary arteries and veins. The formation of noncaseating granulomas is likely preceded by alveolitis involving the interstitium more than the alveolar spaces. There is accumulation of inflammatory cells, including monocytes, macrophages, and lymphocytes that accompany the granulomas. Multinucleated giant cells are frequently found among the epithelioid cells within the granuloma follicle. These may show cytoplasmic inclusions (e.g., asteroid bodies and Schaumann bodies) as well as some birefringent crystalline particles made of calcium oxalate and other calcium salts. These are most often identified in the upper lobes of the lungs which may lead to confusion with diseases such as hypersensitivity pneumonitis, eosinophilic granuloma, collagen vascular disease, pneumoconiosis, berylliosis, and infectious disease such as tuberculosis or histoplasmosis.

Radiology

Pulmonary imaging in sarcoid has included plain chest radiography, HRCT, **positron emission tomography** using fluorine-18-fluorodeoxyglucose, and radiotracer using gallium-67. The staging of sarcoid is performed using plain radiography and is outlined as follows:

- Stage I—Bilateral hilar lymphadenopathy accompanied by right paratracheal lymphadenopathy
- Stage II—Bilateral hilar lymphadenopathy accompanied by reticular opacities are present. If symptomatic, patients have cough and dyspnea. Occasional fever and fatigue accompany the respiratory symptoms.
- Stage III—Reticular opacities are found predominantly in the upper lobes with regression of hilar lymphadenopathy.
- Stage IV—Reticular opacities start to coalesce and lead to volume loss in the lung fields, traction bronchiectasis from conglomeration of the inflamed tissues. Extensive calcium deposits may be seen at this stage.

HRCT may be helpful in further staging of the disease, as well as in revealing abnormalities not appreciated on chest radiography. Findings in patients with sarcoidosis by HRCT include hilar lymphadenopathy, paratracheal nodules, middle to upper lung parenchymal ground-glass appearance, bronchial wall thickening, bronchiectasis, cystic changes, and fibrosis. The ground-glass appearance suggests that alveolitis, as seen in hypersensitivity pneumonitis, may be present. Biopsy has usually shown granuloma formation as the predominant histologic finding.

Treatment

Because pulmonary sarcoidosis spontaneously resolves without therapy in almost 75% of patients, clear guidelines for treatment focused on minimizing side effects of therapy is required. Glucocorticosteroids (GCSs) have long been the mainstay of therapy in sarcoid and are often used because of extra pulmonary disease. When pulmonary disease is progressive, GCS therapy is aimed at prevention of fibrosis, honeycombing, and irreversible lung disease. Assuring that disseminated infections, heart failure, thromboembolism, or pulmonary hypertension are not present is important. In addition to HRCT of the chest, performance of pulmonary function tests, electrocardiogram and echocardiogram should be considered prior to starting GCS therapy.

GCS therapy is often not started when stage I or II is present without symptoms. This scrutiny of the benefit of therapy was highlighted when prospective evaluation of GCS therapy for pulmonary disease found that nearly 50% of patients receiving GCSs had active or relapsing disease 2 yr later. In contrast, 90% of patients who did not receive GCSs had spontaneous remission of disease with the other 10% needing intervention 2 yr later. Absolute indications include progressive stage III disease with symptoms of shortness of breath, cough, or other chest symptoms such as pain. Progressive restriction shown on pulmonary function testing is an indication for therapy. Specific pulmonary function changes where lung capacity declines total 10% or greater, forced vital capacity declines 15% or more, or diffusion capacity degradation is seen of 20% or more are all indications for GCS intervention.

Dosage with oral prednisone at 0.3-0.5 mg/kg is a reasonable starting point depending on the severity of symptoms. Stability is usually achieved within 6-8 wks, after which slow progressive tapering of GCS may occur every 4-8 wks. Many favor the use of alternate-day steroids to reduce the side effects of GCSs, but little data exist to show efficacy.

Patients who do not tolerate GCSs or develop progressive disease, alternative immunosuppressive agents may add benefit to the regimen. Progressive disease also is a reminder for the clinician to reassess the diagnosis of sarcoid and review the chance that beryllium may have been the underlying reason for the progressive disease.

Inhaled GCSs have been evaluated in patients with stage I disease with variable results. Evaluation of therapy with pulmonary function testing and symptoms are the best methods to judge responsiveness to this therapy. Persistent symptoms after 4-8 wks of therapy suggest that systemic GCSs may be indicated.

BERYLLIOSIS

Chronic beryllium disease or berylliosis is an example of environmental exposure and unique granulomatous response in the lungs. Beryllium is an alkaline metal that is used in a number of industrial settings.

A diagnosis of berylliosis requires 3 criteria: (1) history of beryllium exposure; (2) positive response to lymphocyte proliferation tests to beryllium in lymphocytes obtained by BAL or blood test; and (3) noncaseating granulomas on lung biopsy. Exposure to beryllium may occur in industries such as automotive, ceramic, aerospace, metal extraction, electronics, computer, jewelry making, and dental alloys. Teenagers working summer jobs in machine work, ceramics, or wire production may be exposed. Sensitization is associated with dose and duration of exposure and has been seen to be as high as 20% in certain industries. Secretaries working in buildings where manufacturing with beryllium is active have developed berylliosis.

Pathogenesis

Genetic susceptibility coupled with immunologic response to beryllium are the 2 key contributors to the development of disease. A T-lymphocyte cell–mediated delayed hypersensitivity response to beryllium appears to be the mechanism involved with granuloma formation in the lung. The lymphocyte proliferation by T cells to beryllium is specific and does not occur to other metals. Similar to sarcoidosis, CD4+ T cells predominate on bronchoalveolar response. Beryllium appears to be inhaled and then couple with proteins in the lung or can be ingested by antigen-presenting cells. The cytokines elicited and granuloma formation suggests that sensitization is primarily a T-lymphocyte type 1 response with elevated interferon-γ and IL-2 production.

Clinical Manifestations

The clinical manifestations of berylliosis are not specific. Dry cough, fever, fatigue, weight loss, and shortness of breath all may be present. Although symptoms may occur within 3 mo, new disease has been detected up to 3 decades after exposure. Physical examination is somewhat different than the HPs and sarcoid with bibasilar crackles found on auscultation. The other mentioned diseases are more prominent in the upper lobes. Small nodule on exposed skin may also be present.

Laboratory Testing

Suspicion of berylliosis should prompt the clinician to have blood lymphocyte proliferation studies to beryllium performed as well as complete pulmonary functions. These tests need to be sent to a special center where multiple tests are run with comparison to proper positive and negative controls. When positive, the test has very high specificity for defining the presence of berylliosis at approximately 96%. However, sensitivity of the test hovers at <70%, suggesting that approximately 3 of every 10 patients who have disease may have a negative test.

Similar to other pulmonary granulomatous diseases, increased production of calcitriol is commonly found. The source of this active form of vitamin D is from activated pulmonary macrophages, which may result in hypercalciuria and hypercalcemia.

Radiography

Chest radiographs should be obtained on all patients suspected of having berylliosis. The chest radiograph may be normal, show hilar lymphadenopathy, pulmonary nodules, ground glass, or alveolar opacities. The parenchymal abnormalities may be diffuse or may be more prominent in the upper lobes. These findings are dependent upon the stage of the disease.

HRCT is the most sensitive test in the identification of chronic berylliosis. Almost 25% of the HRCT exams in patients with biopsy proven berylliosis are found to be normal. Similar to other granulomatous and HPs of the lungs, HRCT findings include parenchymal nodules of varying size, thick septal lines, ground-glass opacities, cystic cavitation, and lymphadenopathy in the hilum or mediastinum. Pleural abnormalities are less common, but thickening may be observed in proximity to parenchymal nodules.

Treatment

Managing berylliosis involves avoiding further exposure and therapy with glucocorticoids or other immunosuppressive agents. A decision to intervene depends on the severity of symptoms, physiologic impairment based on pulmonary function tests, and extent of radiographic changes. Treatment is usually started when the patient has dyspnea or cough, >10% decline in lung volumes or gas exchange, or abnormal pulmonary function tests at baseline.

Small case series have demonstrated efficacy of steroids judged by improvement of clinical symptoms, radiographic clearing of disease, and improvement in pulmonary functions, including diffusion capacity. Some patients despite improved symptoms have recurrence which may progress to fibrosis and persistent lung disease.

The differentiation between berylliosis and sarcoidosis appears to be important for long-term outcomes. It appears that the longer the delay in prescribing GCSs to patients with berylliosis may lead to a state where the lung disease is unresponsive to therapy. In contrast, use of steroids may lead to a higher rate of recurrent disease. What makes the 2 responses different is not known.

Dosing of steroids is similar to sarcoid with a starting dose of 0.5 mg/kg/day of prednisone for a duration of 6-12 wks. Once a response is established, conversion to every-other-day corticosteroid use at the same dose followed by tapering should be attempted until the lowest dose is achieved that controls the disease. Patients may require persistent therapy for the rest of their life. Genetic susceptibility to the disease may predict relapse of disease. Mutations in the HLA-DPB1 gene (homozygous for glutamate substitution at the β69 position) appear to predict specific patients who are susceptible to relapse of symptoms.

When patients fail to respond or experience recurrent relapse, methotrexate in low dose has conferred a favorable response in some patients as has been seen with sarcoidosis. Azathioprine may also be considered since sarcoidosis has responded favorably, however there are no published trials using this immunosuppressive agent. A small number of cases have also shown promise with TNF-α inhibitors both in sarcoid and beryllium-induced disease.

GRANULOMATOUS LUNG DISEASE IN PRIMARY IMMUNE DEFICIENCY

Primary immune deficiency (PID) often presents with recurrent or persistent pulmonary symptoms of recurrent infections, pneumonia, bronchiectasis, and interstitial lung disease with or without fibrosis. Immune dysregulation occurs in many of the PID with development of granulomatous lung disease and autoimmune disease. Most effort is focused on discovery of infectious pathogens in the PID causing pulmonary disturbance, but the dysregulation may be the primary problem causing symptoms and disease progression. This requires counterintuitive therapies with suppression of the immune system concurrently with immune deficiency therapy. The 2 most prominent PIDs associated with granulomatous lung disease are **chronic granulomatous disease (CGD)** (see Chapter 130) and **common variable immune deficiency (CVID)** (see Chapter 126).

The prototype organism causing granuloma formation in the lung is *Mycobacterium tuberculosis*. Nontuberculous mycobacterial infections also can cause granulomas in the presence of specific PID. These have been seen in impaired IL-12/IL-23/ IFN-γ signaling, or the presence of autoantibodies to IFN-γ. Patients with defective regulation of nuclear factor-kappa B (nuclear factor-kappa B essential modifier defects) have

also been described as well with nontuberculous mycobacteria. The clinician must be certain that this low-virulence organism is not causing disease before therapy for immune dysregulation is considered.

Pathogenesis

CGD is a PID involving multiple defects in the phagocyte nicotinamide adenine dinucleotide phosphate oxidase system, which impairs the respiratory burst capacity to generate reactive species of oxygen (see Chapter 130).

Up to 25% of patients with CVID develop lung disease (see Chapter 126). These pulmonary changes include organizing pneumonia, ILD, mucosa-associated lymphoid tissue lymphoma, and noncaseating granulomas in **granulomatous and lymphocytic interstitial lung disease (GLILD)**. Elevated levels of TNF from TNF polymorphisms have been implicated as a possible mechanism. GLILD is becoming recognized more frequently in CVID. It is defined by the presence of granulomatous and a lymphocytic proliferative pattern in the lung. Granulomas may be found in other organs including bone marrow, spleen, gastrointestinal tract, skin, and liver.

The etiology of GLILD is unknown. In a case cohort study, a majority of subjects with pathology diagnostic of GLILD were found to have human herpesvirus 8 infection of the lung. These may represent a subgroup of patients with GLILD which may point to a mechanism underlying the development of pulmonary granulomas.

GLILD is sometimes misdiagnosed as sarcoidosis initially because both involve pulmonary granuloma, often accompanied by hilar and/or mediastinal lymphadenopathy. Sarcoidosis has several features that distinguish it from GLILD, such as normal or elevated serum immunoglobulin levels and frequent spontaneous remissions.

Clinical Manifestations of Granulomatous Lung Disease in Primary Immune Deficiency

Chronic respiratory disease as a result of recurrent infections is common in CGD. This is accompanied by clubbing in some patients and the other organ manifestations in the skin, liver, and genitourinary and gastrointestinal tracts. Granulomas are especially problematic in the gastrointestinal and genitourinary tracts. The inhalation of fungal spores and hyphae has led to an acute pneumonia in CGD with rapid progression to respiratory failure with hypoxemia, dyspnea, and fever. This entity, characterized as *mulch pneumonia,* appears to be best treated with antifungal medications and corticosteroids.

Radiography

Hilar and/or mediastinal lymphadenopathy occur with granulomatous lung involvement. These may manifest as parenchymal nodules and/or ground glass abnormalities and can be seen commonly in CVID and CGD. Differentiating infectious causes of pulmonary infiltration in PID is often difficult on chest radiography; HRCT is often mandatory in the initial evaluation of the patients with CVID.

Laboratory and Pulmonary Function Testing

Definitive diagnosis is made by lung biopsy. Transbronchial biopsy in children is often insufficient and lung biopsy by video-assisted thoracoscopy or open biopsy is preferred. Unless the patient's underlying immune deficiency is unknown, other laboratory testing except for infectious organisms does not contribute significantly to the diagnosis. When the child is old enough, complete pulmonary functions with spirometry, flow volume loop, lung volumes, and diffusion capacity should be obtained at baseline and then followed serially for response to therapy or progression of disease.

Therapy

The presence of GLILD in CVID can be associated with significant morbidity and possibly death. Without therapy, progressive pulmonary fibrosis and respiratory failure may occur in GLILD. The parenchymal disease may not always be controlled or relieved by glucocorticoid treatment. Other treatments include TNF antagonists, cyclosporine, or a combination therapy with rituximab and azathioprine. Response to therapy is monitored clinically and by interval HRCT of the chest, and pulmonary function testing, including spirometry, lung volumes, and diffusing capacity.

Bibliography is available at Expert Consult.

399.4 Eosinophilic Lung Disease

Kevin J. Kelly

The eosinophilic lung diseases are a group of heterogeneous pulmonary disorders with a predominant diffuse infiltration of eosinophils in the alveolar spaces or interstitial pulmonary spaces. Lung architecture is well preserved throughout the inflammatory response, often with complete reversal of the inflammation without long-term sequelae in the majority of cases. The peripheral white blood count often (but not always) reveals elevated eosinophils. Prompt recognition of the nature of these diseases allows for lifesaving interventions in the idiopathic **acute eosinophilic pneumonia syndrome (AEP)** or resolution of persistent symptoms in the patients with chronic disease.

ETIOLOGY

Eosinophilic lung diseases are often classified under 2 subheadings: idiopathic disease and known causation (Table 399-8). They are frequently further subdivided as acute and chronic or infectious and noninfectious. The division of acute or chronic is arbitrary based on the length of symptoms present (acute = <1 mo and chronic = >1 mo) but is relevant to the clinician in determining the etiology of the symptoms in the differential diagnosis. **Löffler eosinophilic pneumonia**, induced by *Ascaris lumbricoides* and other ascarids, produces transient symptoms that self-resolve and is classified as neither acute nor chronic. Löffler syndrome has been more correctly termed pulmonary infiltrates with eosinophilia syndrome and is the most common eosinophilic infiltrative disease in children.

PATHOLOGY AND PATHOGENESIS

Eosinophilic lung disease, regardless of the stage of disease or etiology, shows mixed cellular infiltration of the alveoli and interstitial spaces with a predominance of eosinophils when transbronchial biopsy or open lung biopsy is performed. This may be accompanied by a fibrinous exudate with intact lung architecture. Other findings include eosinophilic microabscesses, a nonnecrotizing nongranulomatous vasculitis, and occasional multinucleated giant cells again without granuloma formation. BAL is the diagnostic procedure of choice, especially in the acute situation with the acute eosinophilic pneumonias; the differential cell count on the BAL is ≥25% eosinophils and is often more than 40%. This highly sensitive test and high specificity test has allowed clinicians to forego lung biopsy.

Eosinophils are filled with numerous toxic granules. Evidence of eosinophil degranulation may be found by electron microscopy, biopsy, urine excretion, and BAL fluid. Most commonly, eosinophil-derived neurotoxin, leukotriene E_4, other granule proteins, such as major basic protein, Charcot Leyden crystals, or proinflammatory cytokines, are identified and support the evidence that eosinophils are not only present but contributing to the disease process.

CLINICAL MANIFESTATIONS

Specific eosinophilic lung diseases present with a variable clinical picture; however, there are some common findings across many of the eosinophilic diseases. Dyspnea is the most common and prevalent symptom in patients with acute or chronic eosinophilic pneumonia and is accompanied by cough in the majority of patients (90%). Rhinitis and sinusitis symptoms are of lower prevalence with wide variability in children with eosinophilic pulmonary disease. Only the A specific disorder, **acute eosinophilic pneumonia**, consistently presents with respiratory failure and the requirement for mechanical ventilation at high levels of positive end expiratory pressure and high concentrations of oxygen. Although malignancy (e.g., eosinophilic leukemia) and organizing pneumonia may present with need for mechanical

Table 399-8 Key Elements in the Medical History and Physical Exam to Raise Clinical Suspicion for Diagnostic Testing to Confirm Eosinophilic Lung Disease

Medical history and examination

- Drug exposure (especially antibiotics, NSAIDs, antiepileptics, antileukotriene modifiers in EGPA)
- Environmental inhalation exposures to dust or inhaled chemicals
- New onset of smoking cigarettes
- Travel or immigration status from areas endemic with various parasites or coccidiomycosis
- Asthma (may be severe or poorly controlled with ABPA, CSS, or is relatively new in onset with IAEP)
- ABPA concurrent in 7-10% of patients with cystic fibrosis
- Extrapulmonary symptoms suggestive of vasculitis, neuropathy, heart failure, or neoplasm)
- Rash (creeping eruption in visceral larval migrans disease or ulceration in EGPA)

Diagnostic imaging and testing

- Radiography helpful in AEP, CEP, and ABPA
- Radiography not diagnostic in EGPA or drug-induced eosinophilic disease of the lung
- Simple chest radiography findings
  - Nonlobar infiltrate
  - Classic description as mirror image of pulmonary edema with peripheral infiltrates
  - Bilateral pleural effusion in AEP
  - Central bronchiectasis in ABPA
- High-resolution computerized tomography of the chest
  - Middle and upper lobe nonlobar infiltrates with areas of ground-glass appearance
  - Mucous plugging in ABPA
  - Central bronchiectasis in ABPA (confused with cystic fibrosis)
- Blood eosinophil count
  - Elevated in many eosinophilic lung diseases
  - Magnitude of eosinophil blood count does not distinguish different pulmonary diseases
  - Usually not elevated in AEP (eosinophilic disease compartmentalized to lungs)
  - May occasionally not be elevated in CEP or after use of corticosteroids
- Total serum IgE elevated in ABPA but not always in patients with cystic fibrosis with ABPA
- Serology for helminthic infections or parasites may be diagnostic but are usually not available acutely
- P-ANCA (MPO ANCA) is positive in 40-70% of EGPA (CSS)
- BAL eosinophil percentage
  - ≥25% eosinophils diagnostic in AEP
  - ≥40% eosinophils diagnostic in CEP or tropical pulmonary eosinophilia
  - Eosinophil percentages below these criteria may require lung biopsy
  - <25% eosinophils seen in connective tissue disease, sarcoid, drug-induced disease, histiocytosis X of pulmonary Langerhans cells, and interstitial pulmonary fibrosis
- Lung biopsy
  - Open lung biopsy or video-assisted thoracoscopic surgery when BAL nondiagnostic
  - Transbronchial biopsy is usually insufficient with peripheral infiltrative disease
  - Histology with alveolar and interstitial infiltrates of eosinophils, non-necrotizing non-granulomatous vasculitis, multinucleated giant cells without granuloma
  - EGPA shows eosinophil rich small to medium vessel, necrotizing, granulomatous vasculitis

ABPA, allergic bronchopulmonary aspergillosis; AEP, acute eosinophilic pneumonia; BAL, bronchoalveolar lavage; CEP, chronic eosinophilic pneumonia; CSS, Churg-Strauss syndrome; EGPA, eosinophilic granulomatosis with polyangiitis; IAEP, idiopathic acute eosinophilic pneumonia; MPO ANCA, myeloperoxidase antineutrophil cytoplasmic antibody; NSAID, nonsteroidal antiinflammatory drug; P-ANCA, perinuclear antineutrophil cytoplasmic antibody.

ventilation, they are less common. A history of asthma is common in the chronic eosinophilic pneumonias and in allergic bronchopulmonary aspergillosis (ABPA) and often precedes the diagnosis of these 2 conditions.

Other symptoms of fever, myalgia, fatigue, weight loss, poor appetite, and night sweats may accompany the acute or chronic eosinophilic pneumonias. When abnormalities of the liver are detected, or if arthralgia, skin changes, pericardial effusion, or peripheral neuropathy accompany the disease presentation, a diagnosis of eosinophilic GPA (formerly known as the Churg-Strauss syndrome) or the hypereosinophilic syndrome should be aggressively investigated.

Chest Imaging

The chest radiograph is one of the most helpful tests in evaluating the child with dyspnea. The characteristic feature of fluffy alveolar infiltrates in the peripheral lung field is classic (Fig. 399-5). The images may be easily recognizable by astute clinicians who have identified the etiology of the disease without eosinophil counts or BAL.

HRCT is the best advanced imaging modality for eosinophilic lung disease. Spontaneous migration of lung opacities is commonly seen in the chronic pneumonias. Most often HRCT shows simultaneous evidence of bilateral alveolar infiltrates with both confluent consolidations and ground glass appearance. The most prominent areas of abnormality are visualized in the upper lobes and subpleural regions. Specific diseases have unique findings, such as proximal bronchiectasis in ABPA and pleural effusion in acute eosinophilic pneumonia. HRCT is most sensitive in identifying the correct etiology of disease when chest radiographic findings are nonspecific.

LÖFFLER SYNDROME

The transient pulmonary infiltrates with eosinophilia syndrome that is most often seen in children (formerly known as Löffler syndrome) is characterized by migrating pulmonary infiltrates with peripheral blood eosinophilia caused by the helminthic infections. *A. lumbricoides* or roundworm is the most common parasite causing this disease in the United States. When a fertilized egg is ingested from contaminated food, it becomes a larval worm that can penetrate the duodenum of the small intestine and migrate in the circulation to the liver, heart, and lungs. In the pulmonary venous circulation, the larvae can break through the interstitial space to the alveoli. The juvenile larva may subsequently migrate to the trachea where they are coughed up and swallowed. The cycle may then recur with subsequent absorption of eggs that are produced in the intestinal track. Other nematodes cannot mature in the intestinal tract so their disease is limited to a single passage into the lungs.

Visceral larva migrans from multiple nematodes may cause this disease. The most common cause of these includes the dog roundworm, *Toxocara canis*, while *Toxocara cati, Strongyloides stercoralis, Baylisascaris procyonis,* and *Lagochilascaris minor* can all produce visceral larva migrans. Outside the United States, the common lung fluke, *Paragonimus westermani*, may cause a similar pulmonary disease in older children and adolescents. Western Africa, Central and South America, and the Far East are regions that paragonimiasis may be found, especially in those who eat raw crabs or crawfish. Many other parasites may have a transient pulmonary syndrome, but their diseases are most commonly manifested in other organs.

The pulmonary syndrome is classic with cough, dyspnea, migratory peripheral pulmonary infiltrates, and blood eosinophilia that is self-limited. Young children most often have a history of pica and eating dirt that is contaminated with the eggs. Because the larva can migrate to other organs as well as multiply in the intestinal and biliary tract, symptoms of abdominal pain, vomiting, rarely obstruction, cholecystitis, and pancreatitis may be found. Diagnosis is frequently made by examination of the stool where the eggs may be detected microscopically. Treatment is aimed at the intestinal disease and not the pulmonary disease per se. It is possible that antihelminthic treatment of other organ disease during the pulmonary phase of the disease will increase the inflammatory response in the lung and may require corticosteroid therapy.

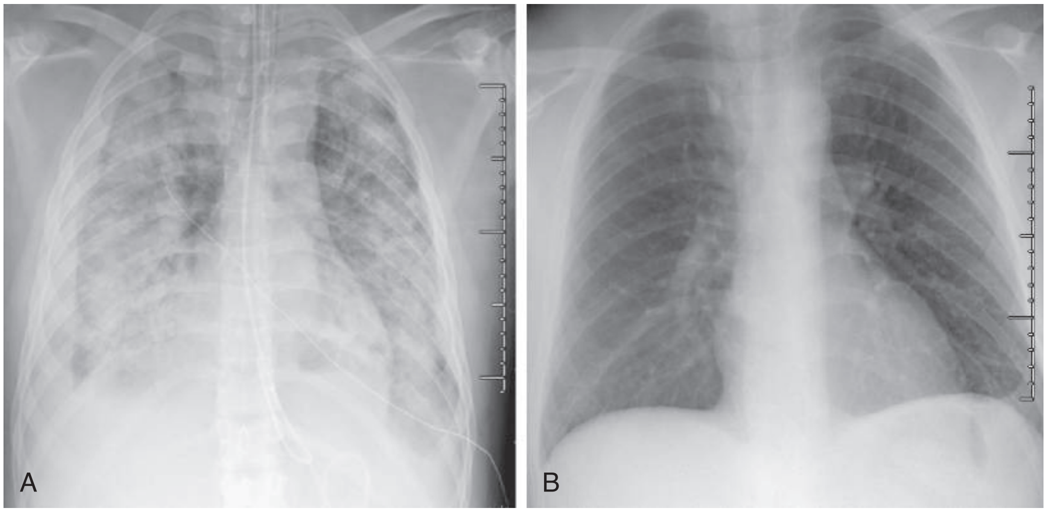

Figure 399-5 Acute eosinophilic pneumonia demonstrating the mirror image **(A)** pulmonary edema with a right pleural effusion on admission and **(B)** complete clearing upon discharge from the hospital after corticosteroid usage.

ACUTE EOSINOPHILIC PNEUMONIA

A unique and dramatic presentation of the eosinophilic pneumonias is AEP. AEP mimics infectious pneumonia or acute respiratory distress syndrome with its rapid onset and marked hypoxemia. In pediatrics, this disease most frequently occurs in the teenage population. Overall, young adults most commonly contract this idiopathic disease. Essentially all patients present within 7 days of symptom onset with dyspnea, fever, and cough, and more than 50% have chest pain. Myalgia and abdominal pain also frequently accompany this disease. Rarely, patients have presented up to 4-5 wks after onset of symptoms. Physical exam demonstrates tachypnea, tachycardia, and crackles in the lung fields on physical exam. Many patients rapidly deteriorate and require mechanical ventilation.

There is an absence of circulating eosinophilia, which contrasts the dramatic number of eosinophils seen in the BAL representing at least 25% of the inflammatory cells (often 40-55%) (Fig. 399-6). This feature helps distinguish it from the chronic pulmonary disease of eosinophilic origin.

Although this disease has been labeled as idiopathic, there have been identifiable exposures (e.g., 1,1,1-trichloroethane or Scotchgard). Numerous reports link onset of smoking tobacco, change in smoking frequency, reinitiation of smoking in young male adolescents or adults, and even massive secondary smoke exposure as critical associations with onset of AEP. World Trade Center dust is associated with development of AEP. A single smoke challenge study is associated with recurrence. Some medications are also linked to the onset of AEP. The most complete and current resource for medications linked to pulmonary disease is "The Drug-Induced Respiratory Disease Website" (http://www.pneumotox.com). When AEP is identified in a patient, the pediatrician's role in educating the patient and family about the link to smoking exposure and risk of AEP upon reexposure is warranted.

In addition to smoke exposure, AEP has been reported after smoking cocaine within hours to days after exposure. Whether this is a unique eosinophilic response to cocaine that represents one manifestation of "crack lung" or is a separate disease is unknown. "Crack lung" refers to diffuse alveolitis with pulmonary hemorrhage from an unknown mechanism that occurs within 48 hr of cocaine smoke inhalation.

Lung function has not been measured frequently in the disease because the patients have proceeded rapidly to the ICU and need for mechanical ventilation. When measured, a restrictive pattern of lung disease and reduced diffusion capacity is the usual finding arterial blood gases will show a significant increase in the alveolar–arterial gradient (see Chapter 373).

The criteria for diagnosis include the acute onset of disease, bilateral pulmonary infiltrates, reduced oxygen saturation or Pa_{O_2} ≤60 mm Hg, BAL of ≥25%, and absence of a determined cause of eosinophilia. The recent onset of tobacco exposure, dust, or chemical inhalation is supporting factors in confirming a diagnosis.

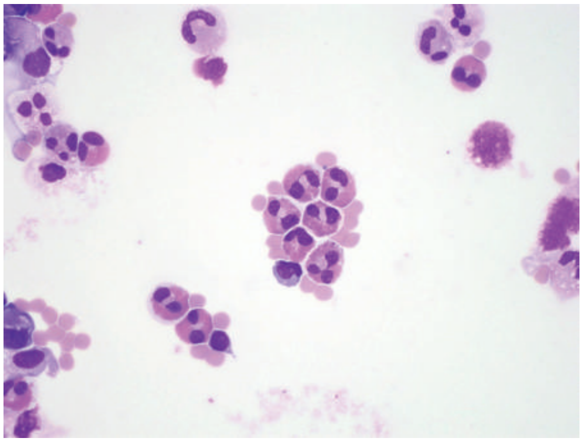

Figure 399-6 Light microscopy of eosinophils in bronchoalveolar lavage fluid.

Treatment has uniformly been the use of a corticosteroid (e.g., methylprednisolone 1-2 mg/kg/day) either intravenously or orally for 2-4 wks. A minimum or maximum treatment time has not been determined, but relapses or persistent symptoms are uncommon. Rare fatalities have been reported. Complete recovery has been seen in days with resolution of pleural effusions within the 4 wk treatment time. Most important, relapse has been rare, which sharply contrasts the idiopathic chronic eosinophilic pneumonias. Follow-up testing of pulmonary functions are usually normal which supports the contention that lung parenchyma heals without evidence of compromise or fibrosis.

CHRONIC EOSINOPHILIC PNEUMONIA

Chronic eosinophilic pneumonia is another idiopathic pulmonary condition without a known exposure to toxin, dust, or chemical inhalation. Eosinophils infiltrate the lung parenchyma resulting in dyspnea, cough, fever, and weight loss. It is primarily a problem for adults, with a female predominance (2:1 female:male ratio) usually in patients who are nonsmokers. Chest examination reveals tachypnea, crackles, and occasional wheezing as preceding asthma is a common finding. The classic finding on chest x-ray of the "radiographic negative of

pulmonary edema" is found in these patients: central clear lung fields but fluffy, patchy peripheral infiltrates of the lung parenchyma.

When compared to AEP, the onset of disease is indolent and subtle but the accompanying fever and weight loss may lead the clinician to a concern for an underlying malignancy prior to chest radiograph and laboratory investigation. Peripheral blood eosinophilia is commonly as high as 5000/mm^3 or greater, accompanied by BAL eosinophilia >40% on the differential count. The peripheral eosinophilia sharply contrasts the lack of eosinophils seen in the blood in AEP. HRCT scan contrasts the AEP with pleural effusion as a rare finding, as well as rare cavitation.

In contrast to AEP, pulmonary function testing shows a mixed obstructive and restrictive pattern as a result of asthma occurring concurrently with pneumonia.

Inflammatory markers associated with migration and activation of eosinophils are predictably found in BAL and the urine. These include the T-lymphocyte type 2 cytokines of IL-4, IL-5, IL-6, IL-10, IL-13, and IL-18. However, T-lymphocyte type 1 cytokines of IL-2 and IL-12 are also present with many of the potent eosinophilic chemoattractants such as CCL5 (RANTES [regulated upon activation, normal T cell expressed and secreted]) and CCL11 (eotaxin-1). Toxic granule proteins of major basic protein, eosinophil-derived neurotoxin, and eosinophil cationic protein are frequently present. Unfortunately, these important molecules help confirm the eosinophilic nature of the disease, but their presence adds no additional sensitivity or specificity over the presence of eosinophils on BAL.

Treatment is similar to most eosinophilic lung syndromes where corticosteroids (oral) are the mainstay of treatment. The minimum dose of steroid needed to induce remission is not known, but most clinicians recommend prednisone (or equivalent) at 0.5 mg/kg/day for 2 wks. The dose is reduced to half (0.025 mg/kg/day) for an additional 2 wks if symptoms have abated. The remaining dose of steroid may need to be weaned over 6 mo. Symptoms and pulmonary infiltrates rapidly disappear after initiation of this treatment but frequently recur with tapering of the steroid. Asthma concurrently in patients with chronic eosinophilic pneumonia identifies a phenotype of the disease that appears to have lower relapse risk yet up to 50% of all identified patients with chronic eosinophilic pneumonia relapse during or after corticosteroid taper.

Many believe that this disease is a precursor to the development of **eosinophilic granulomatosis with polyangiitis (EGPA)** or the Churg-Strauss syndrome. The utility of inhaled corticosteroids in chronic eosinophilic pneumonia is unknown but is warranted for the persistent asthma phenotype of disease. A subset of patients develop permanent lower airway obstruction without reversibility, which requires patients with this disease to have close follow-up and monitoring of pulmonary function tests routinely.

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS (THE CHURG-STRAUSS SYNDROME)

The EGPA syndrome is a systemic disease involving multiple organs but most prominently the lung. Patients present with difficult to control asthma, allergic rhinitis, and peripheral eosinophilia (>10% or >1,500 cells/μL) in the blood. Evidence of vasculitis on clinical grounds must be present in at least 2 organs. The polyangiitis appears later in the disease process with asthma being the precursor symptom in more than 90% of the cases reported. EGPA affects multiple organs including the skin, heart, gastrointestinal tract, kidneys, and central nervous system. Rhinitis is present in 75% of the patients but is not specific. Symptom complexes of fever, weight loss, fatigue, arthralgia, and myalgia may be seen in approximately two-thirds of patients. Cardiac and renal involvement is insidious in onset and should be screened for. It is the multiple organ involvement that results in the morbidity and mortality of this disease. The typical progression of the disease is in 3 phases: rhinitis and asthma first, tissue eosinophilia second, and, finally, systemic vasculitis.

The pathogenesis of EGPA is still unknown but several factors are suspected to contribute to the development of the disease. The possible link between leukotriene-receptor antagonists (zafirlukast, montelukast, or pranlukast) is controversial but still considered possible. It is suspected that use of this class of adjunctive medications in severe asthma allows for the reduction in use of corticosteroid leading to the full blown (unmasking) manifestation of EGPA. Isolated use of leukotriene-receptor antagonists may induce disease, lead to remission with cessation of leukotriene-receptor antagonists, and cause recurrence of EGPA upon reintroduction of this class of medications. Many refrain from use of leukotriene-receptor antagonists when the EGPA syndrome has been diagnosed.

Clinical and laboratory finding are able to pinpoint the diagnosis with high specificity (99.7%) and sensitivity (85%) when 4 of 6 criteria are met (asthma, eosinophilia >10%, mononeuropathy or polyneuropathy, nonfixed pulmonary infiltrates, paranasal sinus abnormalities, and biopsy findings of extravascular eosinophil infiltrates). In contrast to GPA, the rhinitis is not destructive and nasal septal perforation does not occur in EGPA.

Radiography of the chest by plain radiography or HRCT demonstrates the migratory, peripheral predominant opacities with ground-glass appearance to full consolidation. Bronchiectasis and bronchial wall thickening are reported. Pleural effusion should raise suspicion for the presence of heart failure from cardiomyopathy.

Laboratory findings include striking eosinophilia with values generally between 5,000 and 20,000/mm^3 at the time of diagnosis. These counts often parallel the vasculitis activity that is found. The BAL shows striking eosinophilia with differential counts of >60%. Other organ system levels reflect activity of eosinophils and are not specific for the EGPA diagnosis.

ANCAs are present in the EGPA syndrome. The **perinuclear-ANCA targeting myeloperoxidase** are specifically found in EGPA in approximately 40% of the patients; the absence of myeloperoxidase-ANCA does not exclude the diagnosis. Those patients with eosinophilic pneumonia, fever, and cardiac involvement are less likely to have myeloperoxidase-ANCA detected. Those with peripheral neuropathy, renal glomerular disease, and skin purpura usually have detectable myeloperoxidase-ANCAs.

Pulmonary function tests while on bronchodilators and inhaled corticosteroids for asthma show an obstructive pattern. The pulmonary obstruction is responsive to oral corticosteroid use but often has mild persistence of obstruction.

Treatment of EGPA with systemic oral corticosteroid remains the mainstay of therapy at a starting dose of 1 mg/kg/day for 4 wks. This therapy is often required for up to 12 mo or longer with a steady taper in dosage over that time. EGPA resistant to corticosteroid has responded to cyclophosphamide, IFN-α, cyclosporine, intravenous immunoglobulin, and plasmapheresis. The use of anti–IL-5 (mepolizumab) has been encouraging and may be used as a steroid-sparing agent in the future.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

ABPA is a complex mixed immunologic hypersensitivity reaction in the lungs and bronchi in response to exposure and colonization of *Aspergillus* species (usually *Aspergillus fumigatus*; see Chapter 237.1). This disease almost exclusively occurs in patients with preexisting asthma and up to 15% of patients with cystic fibrosis (see Chapter 402). The quantity of *Aspergillus* exposure does not correlate to the severity of disease.

The clinical pattern of disease (Table 399-9) is remarkably similar with a clinical presentation of difficult-to-treat asthma, periods of acute obstructive lung disease with bronchial mucous plugs, elevated total IgE antibody, elevated specific IgE and IgG anti-*Aspergillus* antibodies, skin prick test reactions to *Aspergillus* species, precipitating antibody to *Aspergillus* species, as well as proximal bronchiectasis. Other clinical manifestations include dyspnea, cough, shortness of breath, production of brown mucous plugs frequently characterized as "rubber" plugs, and peripheral eosinophilia, as well as pulmonary eosinophilia with infiltration of the parenchyma. The use of systemic corticosteroid may lower the total IgE antibody levels such that

Table 399-9 The Classification of the Eosinophilic Lung Diseases

IDIOPATHIC	KNOWN ETIOLOGY
Acute eosinophilic pneumonia	Drug-induced eosinophilic pneumonia
Chronic eosinophilic pneumonia	Infectious causes
Eosinophilic granulomatosis with polyangiitis	• Ascariasis (Löffler syndrome)*
Hypereosinophilic syndromes	• *Toxocara* (*canis* or *cati*)
• Myeloproliferative variant	• Filarial (tropical filarial eosinophilic pneumonia)
• Lymphocytic variant	• *Strongyloides stercoralis* Allergic bronchopulmonary aspergillosis Toxic • L-Tryptophan (eosinophilia myalgia syndrome) • Toxic oil syndrome Illicit drug use (cocaine, heroin, cannabis)

*Note: Löffler eosinophilic pneumonia has transient symptoms and is often classified as neither an acute or chronic eosinophilic pneumonia.

a diagnosis may be in question when the first tests are performed at that time.

ABPA should be considered in patients with cystic fibrosis when clinical deterioration occurs without evidence of an identifiable cause. Symptoms heralding such deterioration include increasing cough, wheezing, loss of exercise tolerance, worsening exercise-induced asthma, reduction of pulmonary function, or increased sputum production without another discernible reason. Clinical findings of elevated total IgE antibody, anti-*Aspergillus* IgE, precipitating antibodies to *A. fumigatus*, and/or new abnormalities on chest radiography that fail to clear with antibiotics should alert the clinician to the possibility of ABPA.

When evaluating a child with asthma symptoms, the clinician must distinguish asthma from ABPA. If the diagnosis is suspected, skin prick test for evidence of IgE-specific antibody directed against *A. fumigatus* is essential. Intradermal skin testing when the skin prick test is negative, although not routinely performed because of poor specificity, may be performed. The absence of a positive skin prick test and intradermal test to *A. fumigatus* virtually excludes the diagnosis of ABPA. The prevalence of ABPA in patients with an existing diagnosis of asthma and an abnormal immediate skin prick test response to *A. fumigatus* has been evaluated. Between 2% and 32% of patients with asthma with concurrent skin prick test–positive reactions to *Aspergillus* have evidence of ABPA.

It is uncommon for the patient with cystic fibrosis to develop ABPA before the age of 6 yr. When the total IgE antibody in patients with cystic fibrosis exceed 500 IU/mL (1,200 ng/mL), a strong clinical suspicion of ABPA is necessary.

ABPA pathology has characteristic findings of mucoid bronchi impaction, eosinophilic pneumonia, and bronchocentric granulomas in addition to the typical histologic features of asthma. Septated hyphae are often found in the mucus-filled bronchial tree. However, the fungi do not invade the mucosa in this unique disease. *Aspergillus* may be cultured from sputum in more than 60% of ABPA patients. Interestingly, hyphae may not always be seen on microscopy.

Staging of the disease (Table 399-10) represents distinct phases of the disease but do not necessarily progress in sequence from stage 1 to stage 5. Staging of ABPA is important for treatment considerations. In many hypersensitivity diseases where IgE antibody contributes to the pathogenesis (e.g., asthma), total IgE is often used for screening for an atopic state, but is not a test that helps the clinician with serial

Table 399-10 Criteria for the Diagnosis of Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis–central bronchiectasis
- Medical history of asthma*
- Immediate skin prick test reaction to *Aspergillus* antigens*
- Precipitating (IgG) serum antibodies to *Aspergillus fumigatus**
- Total IgE concentration >417 IU/mL (>1000 ng/mL)*
- Central bronchiectasis on chest CT*
- Peripheral blood eosinophilia >500/mm^3
- Lung infiltrates on chest x-ray or chest HRCT
- Elevated specific serum IgE and IgG to *A. fumigatus*

Allergic bronchopulmonary aspergillosis seropositive†
- Medical history of asthma†
- Immediate skin prick test reaction to *A. fumigatus* antigens†
- Precipitating (IgG) serum antibodies to *A. fumigatus*†
- Total IgE concentration >417 IU/mL (>1000 ng/mL)†

Staging of allergic bronchopulmonary aspergillosis

Stage 1	Acute	Upper and middle lob infiltration	High IgE
Stage 2	Remission	No infiltrate off steroids >6 mo	Normal to high IgE
Stage 3	Exacerbation	Upper and middle lobe in filtrations	High IgE
Stage 4	CSD asthma	Minimal infiltrate	Normal to high IgE
Stage 5	End stage	Fibrosis and/or bullae	Normal

*The criteria required for diagnosis of ABPA with central bronchiectasis.
†The first 4 criteria are required for a diagnosis of seropositive ABPA.
CSD, corticosteroid dependent.

measures. In sharp contrast, the measurement of IgE during acute exacerbations, remission, and recurrent ABPA disease is helpful in identifying the activity of disease and may herald the recurrence. During stage 1 disease, the level of IgE antibody is often very high. During stage 2 remission, a fall in the levels may be as much as 35% or more. Recurrence of activity may result in a marked rise of total IgE with a doubling of the baseline level seen during remission. During the use of glucocorticoid therapy, monthly or bimonthly levels of IgE are followed serially to assist the clinician in tapering therapy. Because exacerbations of ABPA are asymptomatic to the patient in approximately 25% of the recurrences, serial IgE accompanied by chest radiography are helpful to the clinician to guide therapy.

Radiography

Plain chest X-ray shows evidence of infiltrates especially in the upper lobes and the classic findings of bronchiectasis (Fig. 399-7). The use of HRCT demonstrates central bronchiectasis in the central regions of the lung (Fig. 399-8). HRCT may add value in the patient with a positive skin prick test and normal chest radiograph in detecting characteristic abnormalities of ABPA.

Treatment

The mainstay of therapy for ABPA has been systemic glucocorticoids with adjunct therapy with antifungal medications and anti-IgE therapy with omalizumab. Exacerbations in stages 1 and 3 are treated for 14 days with 0.5-1 mg/kg of glucocorticoid followed by every-other-day usage and tapering over 3 mo or as long as 6 mo. Stage 2 remission phase and stage 5 where fibrosis has occurred do not require glucocorticoid therapy. Stage 4 denotes a state where glucocorticoid weaning has not been successful and continued long-term therapy is required.

Antifungal therapy with a 16 wk course of itraconazole improves the response rate during exacerbations that allowed reduction of glucocorticoid dosage by 50% accompanied by a reduction of total serum IgE of 25% or more. The proposed mechanisms of action have been to either reduce the antigen load driving the immune response or possibly raising the serum levels of corticosteroid by slowing the metabolism

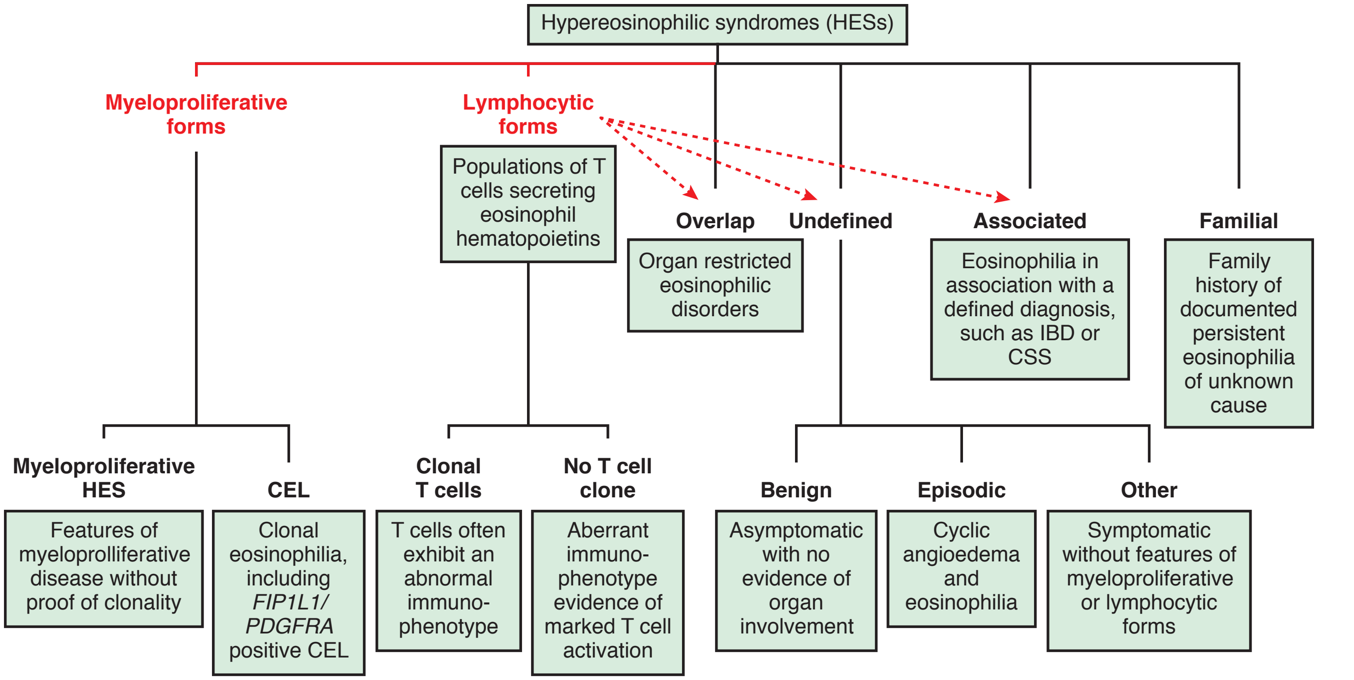

Figure 399-7 A revised classification of hypereosinophilic syndrome (HES). Changes from the previous classification are indicated in red. *Dashed arrows* identify HES forms for which at least some patients have T-cell–driven disease. Classification of myeloproliferative forms has been simplified, and patients with HES and eosinophil hematopoietin-producing T cells in the absence of a T-cell clone are included in the lymphocytic forms of HES. CSS, Churg-Strauss syndrome; IBD, inflammatory bowel disease. *(From Simon H, Rothenberg ME, Bochner BS, et al. Refining the definition of hypereosinophilic syndrome.* J Allergy Clin Immunol *126:45–49, 2010, Fig. 1.)*

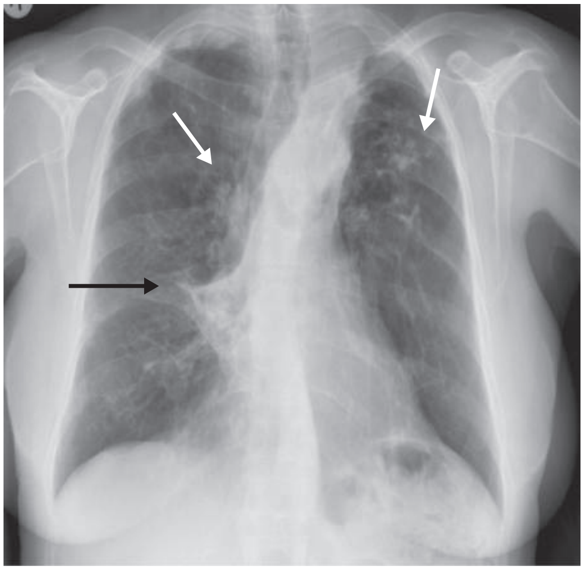

Figure 399-8 Transitory opacities *(white arrows)* and lobar collapse *(black arrow)* in patient with allergic bronchopulmonary aspergillosis. *(From Douglass JA, Sandrini A, Holgate ST, O'Hehir RE: Allergic bronchopulmonary aspergillosis and hypersensitivity pneumonitis. In Adkinson AF, editor:* Middleton's allergy principles and practice, *Philadelphia, 2014, Elsevier, Fig. 61-2.)*

of the steroid. This latter mechanism would be true for prednisone, which is methylated in the liver, but not for methylprednisolone, which does not require methylation.

The adult dosage recommendation for itraconazole is 200 mg 3 times per day for 3 days followed by 200 mg twice daily for the remainder of the 16 wks. Children should receive 5 mg/kg/day in a single dose. If the proper calculated dose exceeds 200 mg, then the total dose should be divided equally and given twice daily. Serum levels of itraconazole are necessary to ensure proper absorption of the drug is occurring from the capsule form. The liquid form is more readily absorbed and has achieved levels substantially higher. The use of proton pump inhibitors and histamine 2 antagonists may reduce absorption from blockade of acid production. Voriconazole has been used as a substitute antifungal medication. Proper dosing has been established for invasive *Aspergillus* disease, but not for ABPA. Typical dosage regimen in children of 7 mg/kg/day may cause hepatotoxicity and liver function must be monitored.

Omalizumab, an anti-IgE humanized monoclonal antibody, has been used in case series of patients with cystic fibrosis and ABPA as well as a small cohort of adults without cystic fibrosis but with ABPA. Both case series demonstrated significant reductions in asthma exacerbations, ABPA exacerbations, and glucocorticoid usage. The dose prescribed has been 300-375 mg every 2 wk by subcutaneous injection.

HYPEREOSINOPHILIC SYNDROME

See Chapter 129.

The hypereosinophilic syndrome (HES) is a descriptive name of a group of disorders that are characterized by the persistent overproduction of eosinophils accompanied by eosinophil infiltration in multiple organs with end-organ damage from mediator release. The term HES should only be used when there is eosinophilia with end-organ damage from the eosinophils and not from another cause. The discovery of underlying genetic, biochemical, or neoplastic reasons for HES has led to the classification of primary, secondary, and idiopathic HES (Table 399-11). Specific syndromes such as EGPA (Churg-Strauss) have eosinophilia but the contribution of eosinophils to the organ damage is incompletely understood.

Some variants of HES have genetic mutations in tyrosine kinase receptor platelet-derived growth factor receptor-α (*PDGFRA*); males are almost exclusively affected. Otherwise, HES appears to be distributed equally among females and males.

Hypereosinophilia is defined as an absolute eosinophil number in the blood that exceeds 1.5×10^9 eosinophils on 2 separate occasions

separated by at least 1 mo. Tissues are abnormal when more than 20% of nucleated cells in the bone marrow are of eosinophil origin; a pathologist determines the presence of eosinophilia; or the presence of extensive eosinophilic granule proteins are determined on biopsy to be deposited in large quantities. These disorders can be subclassified into primary (neoplastic), secondary (reactive), and idiopathic (Fig. 399-9).

Clinical manifestations of the HES include organ involvement of the heart (5%), gastrointestinal (14%), skin (37%), and pulmonary (25%-63%). The HES is complicated by thrombosis and/or neurologic disease in many patients, although the exact prevalence of this problem is incompletely categorized. Peripheral neuropathy, encephalopathy, transverse sinus thrombosis, or cerebral emboli are the most common neurologic complications. The exact mechanism of the manifestations is unclear especially in major artery thrombosis such as the femoral artery.

The most frequent pulmonary symptoms include cough and dyspnea. Many patients have obstructive lung disease with clinical wheezing. Evidence of pulmonary fibrosis and pulmonary emboli are seen with regularity. Because biopsy shows eosinophilic infiltrates similar to other pulmonary eosinophilic diseases of the lung, it is the constellation of other organ involvement or thromboembolic phenomena and other organs that must lead the clinician to a high index of suspicion for the HES.

Table 399-11	Hypereosinophilic Syndrome Variants
Myeloproliferative	Nonclonal Clonal–F1P1L1/PDGFRA-positive chronic eosinophilic leukemia
Lymphocytic	Nonclonal T cells Clonal T-cell expansion with T-cell activation
Overlap	Organ restricted
Familial	Family history of eosinophilia without known cause
Associated	Eosinophilia in chronic disease like inflammatory bowel disease or EGPA (Churg-Strauss syndrome)
Undefined	Asymptomatic Cyclic angioedema with eosinophilia (Gleich syndrome) Symptomatic without myeloproliferation or lymphocytic form

EGPA, eosinophilic granulomatosis with polyangiitis; PDGFRA, platelet-derived growth factor receptor-α.

Laboratory evaluation should include evaluation of liver enzymes, kidney function tests, creatine kinase, and troponin. The extent of cardiac involvement should be evaluated by electrocardiogram and echocardiogram. Some unique biomarkers may be tested when evaluating the myeloproliferative and T-lymphocyte HES diagnoses. Vitamin B_{12} and serum tryptase may be elevated, especially the latter, when the myeloproliferative disease is accompanied by mastocytosis. These 2 biomarkers are most frequently elevated when the mutation is present or fusion in the FIP1L1/PDGFRA sites.

Because of the extensive pulmonary disease that is seen in the HES, pulmonary function tests should be performed at diagnosis when possible to include spirometry and lung volumes. Dead space ventilation may be significantly elevated in the patients with pulmonary emboli. Pulse oximeter may be very helpful in the evaluation as well.

Chest radiography and CT are very helpful in the evaluation. Spiral chest CT should also be performed when pulmonary emboli are being considered. In one series of patients, nearly half of the patients with HES had evidence of pulmonary abnormalities including ground-glass appearing infiltrates, pulmonary emboli, mediastinal lymphadenopathy, and/or pleural effusion.

Treatment of HES depends on the type of variant (myeloproliferative, lymphocytic forms, undefined, associated with systemic diseases such as EGPA or familial). Rarely, some patients present with marked eosinophilia where the total count exceeds 100,000 cells/µL and vascular insufficiency symptoms. Prednisone at 15 mg/kg is indicated to acutely reduce the eosinophil count, after diagnostic tests are performed, when safe. If the patient is unstable, the glucocorticoid should be administered to prevent progression of symptoms. Other acute therapies aimed at reduction of eosinophil counts include vincristine, imatinib mesylate, or even leukophoresis.

When eosinophil counts are not as dramatically elevated, therapy begins with glucocorticoids at 1 mg/kg for patients who do not have the FIP1L1/PDGFRA mutation. Patients with this mutation are resistant to glucocorticoids and initial treatment should begin with imatinib, a tyrosine kinase inhibitor. Because this genetic test is often not readily available, surrogate markers for the presence of this mutation are vitamin B_{12} levels >2000 pg/mL or serum tryptase >11.5 ng/mL. It denotes the presence of resistant disease that should initially be treated with imatinib. The goal of therapy is to reduce and maintain eosinophil counts below 1.5×10^9 at the lowest dose of prednisone possible to reduce or avoid corticosteroid side effects. If corticosteroid doses can't be lowered below 10 mg/day, then imatinib can be added as combination therapy in order to spare the dose of steroid. Caution must be used in the presence of cardiac disease as introduction of imatinib has precipitated left ventricular failure.

Additional or alternative adjunct therapies that have shown promise include hydroxyurea, interferon α, anti–IL-5 monoclonal antibody therapy; and a monoclonal antibody directed against CD52. Failure of

the above modalities may signal a need for hematopoietic stem cell transplantation. This therapy has been successful in some patients.

399.5 Interstitial Lung Disease

Kevin J. Kelly

ILD in children is caused by a large group of uncommon, heterogeneous, familial, or sporadic diseases that involve the pulmonary parenchyma and cause significant impairment of gas exchange. The ILDs in pediatrics are uncommonly caused by infectious processes and specific immunologic processes when compared to adults. The one exception to this is Goodpasture disease with classic antibasement membrane antibodies. Despite wide variations in cause, these disorders are classified together because of the similar clinical, physiologic, radiographic, and pathologic processes involving disruption of alveolar interstitium and airways. A survey of all German pediatric hospitals found a rate of occurrence of pediatric ILD of 1.3 children/million population. The pathophysiology is believed to be more complex than that of adult disease because pulmonary injury occurs during the process of lung growth and differentiation. In ILD, the initial injury causes damage to the alveolar epithelium and capillary endothelium. Abnormal healing of injured tissue may be more prominent than inflammation in the initial steps of the development of chronic ILD. Some familial cases, especially in the surfactant dysfunction disorders, involve a specific genetic mutation.

CLASSIFICATION AND PATHOLOGY

Classification of ILD in children is not standardized. It is helpful for the clinician to separate diseases into ILD on the basis of age, disorders of known and unknown etiology, and diseases related to systemic disorders (Table 399-12). A diffuse developmental disorder of the lung is likely the result of a primary aberration in lung and/or pulmonary vascular development. Growth abnormalities reflecting deficient development of alveoli are largely secondary to impaired prenatal or postnatal alveolarization from restriction of fetal thoracic space, limitation of pulmonary blood supply, or chronic lung disease of prematurity (e.g., bronchopulmonary dysplasia) (see Chapter 101). Abnormal alveolar growth may also be associated with a variety of chromosomal abnormalities such as trisomy 21. In **neuroendocrine cell hyperplasia of infancy**/persistent tachypnea of infancy, a distinct entity limited to infants and young children, the pathologic findings include hyperplasia of neuroendocrine cells within the bronchioles while the pulmonary histologic background is nearly normal. **Pulmonary interstitial glycogenosis** is characterized by diffuse accumulation of mesenchymal cells in the alveolar interstitium with accumulation of monoparticulate glycogen in the interstitial cell cytoplasm that is confirmed by ultrastructural examination.

Disorders associated with **surfactant metabolism dysfunction** explain many of formerly idiopathic pediatric ILDs. The more-severe surfactant dysfunctions, such as surfactant protein-B mutations, usually manifest as respiratory failure in neonate. **Congenital pulmonary alveolar proteinosis** is more typical of *ABCA3* mutations, and **chronic pneumonitis of infancy** is predominant histologic pattern seen in surfactant protein-C mutations. Age-related but overlapping surfactant disorders in addition to pulmonary alveolar proteinosis and chronic pneumonitis of infancy also include **desquamative interstitial pneumonia** in infants; older children and adolescents more often manifest **nonspecific interstitial pneumonia** or **usual interstitial pneumonia**. *ABCA3* mutations may produce pulmonary alveolar proteinosis, desquamative interstitial pneumonia, or nonspecific interstitial pneumonia; surfactant protein-C deficiency may also produce chronic pneumonitis of infancy in older children.

Diffuse ILD can occur without a known immunodeficiency or systemic disorder, but it can also be seen as a pulmonary manifestation of other systemic disease processes, such as collagen vascular disorders and sarcoidosis.

Table 399-12 The Pediatric Interstitial Lung Diseases

AGE-RELATED ILDS IN INFANCY AND EARLY CHILDHOOD
Diffuse developmental disorders
• Acinar dysplasia
• Congenital alveolar dysplasia
• Alveolar capillary dysplasia with misalignment of pulmonary veins (some due to *FOXF1* mutation)
Growth abnormalities reflecting deficient alveolarization
• Pulmonary hypoplasia
• Chronic neonatal lung disease
• Chromosomal disorders
• Congenital heart disease
Neuroendocrine cell hyperplasia of infancy
Pulmonary interstitial glycogenosis (infantile cellular interstitial pneumonia)
Surfactant dysfunction disorders (pulmonary alveolar proteinosis)
• Surfactant protein–B mutation
• Surfactant protein–C mutation
• *ABCA3* mutation
• Granulocyte-macrophage colony-stimulating factor receptor (*CSF2RA*) mutation
ILD DISORDERS WITH KNOWN ASSOCIATIONS
Infectious/postinfectious processes
• Adenovirus viruses
• Influenza viruses
• *Chlamydia pneumoniae*
• *Mycoplasma pneumoniae*
Environmental agents
• Hypersensitivity pneumonitis
• Toxic inhalation
Aspiration syndromes
PULMONARY DISEASES ASSOCIATED WITH PRIMARY AND SECONDARY IMMUNE DEFICIENCY
Opportunistic infections
Granulomatous lymphocytic ILD associated with common variable immunodeficiency syndrome
Lymphoid intestinal pneumonia (HIV infection)
Therapeutic interventions: chemotherapy, radiation, transplantation, and rejection
Idiopathic ILDs
Usual interstitial pneumonitis
Desquamative interstitial pneumonitis
Lymphocytic interstitial pneumonitis and related disorders
Nonspecific interstitial pneumonitis (cellular/fibrotic)
Eosinophilic pneumonia
Bronchiolitis obliterans syndrome
Pulmonary hemosiderosis and acute idiopathic pulmonary hemorrhage of infancy
Pulmonary alveolar proteinosis
Pulmonary vascular disorders
Pulmonary lymphatic disorders
Pulmonary microlithiasis
Persistent tachypnea of infancy
Brain-thyroid-lung syndrome
SYSTEMIC DISORDERS WITH PULMONARY MANIFESTATIONS
Goodpasture disease
Gaucher disease and other storage diseases
Malignant infiltrates
Hemophagocytic lymphohistiocytosis
Langerhans cell histiocytosis
Sarcoidosis
Systemic sclerosis
Polymyositis/dermatomyositis
Systemic lupus erythematosus
Rheumatoid arthritis
Lymphangioleiomyomatosis
Pulmonary hemangiomatosis
Neurocutaneous syndromes
Hermansky-Pudlak syndrome

Persistent pulmonary symptoms can occur after **respiratory infections** caused by adenoviruses, influenza viruses, *Chlamydia pneumoniae*, and *Mycoplasma pneumoniae*. **Aspiration** is a frequent cause of chronic lung disease in childhood. Children with developmental delay or neuromuscular weakness are at an increased risk for aspiration of food, saliva, or foreign matter secondary to swallowing dysfunction and/or gastroesophageal reflux. An undiagnosed tracheoesophageal fistula can also result in pulmonary complications related to aspiration of gastric contents and interstitial pneumonia.

Children experiencing an exaggerated immunologic response to organic dust, molds, or bird antigens may demonstrate hypersensitivity pneumonitis. Children with malignancies may have ILD related to the primary malignancy or an opportunistic infection or secondary to chemotherapy or radiation treatment.

CLINICAL MANIFESTATIONS

A detailed history is needed to assess the severity of symptoms and the possibility of an underlying systemic disease in a patient with suspected ILD. Identification of precipitating factors, such as exposure to molds or birds and a severe lower respiratory infection, is important in establishing the diagnosis and instituting avoidance measures. A positive family history, especially in an affected infant, is suggestive of a genetic or familial disease, such as a surfactant dysfunction. Tachypnea, dyspnea, cough, and failure to thrive are commonly present. The majority of patients develop hypoxia and hypercarbia, usually a late and ominous complication. Symptoms are usually insidious and occur in a continuous, not episodic, pattern. Tachypnea, crackles on auscultation, and retractions are noted on physical examination in the majority of children with ILD, but chest physical examination findings can be normal. Wheezing and fever are uncommon findings in pediatric ILD. Cyanosis accompanied by a prominent P2 heart sound is indicative of severe disease with the development of secondary pulmonary hypertension. Anemia or hemoptysis suggests a pulmonary vascular disease or pulmonary hemosiderosis. Rashes or joint complaints are consistent with an underlying connective tissue disease.

DIAGNOSIS

Radiography

Chest radiographic abnormalities can be classified as interstitial, reticular, nodular, reticulonodular, or honeycombed. The chest radiographic appearance may also be normal despite significant clinical impairment and may correlate poorly with the extent of disease. HRCT of the chest better defines the extent and distribution of disease and can provide specific information for selection of a biopsy site. Volume-controlled full-inspiratory and end-expiratory protocols used during HRCT can provide more information, possibly showing air trapping, ground-glass patterns, mosaic patterns of attenuation, hyperinflation, bronchiectasis, cysts, and/or nodular opacities. Serial HRCT scans have been beneficial in monitoring disease progression and severity.

Pulmonary Function Tests

Pulmonary function tests are important in defining the degree of pulmonary dysfunction and in following the response to treatment. In ILD, pulmonary function abnormalities demonstrate a restrictive ventilatory deficit with decreased lung volumes and reduced lung compliance. The functional residual capacity is often reduced but is usually less affected than vital capacity and total lung capacity. The residual volume is usually maintained; therefore, ratios of functional residual capacity : total lung capacity and residual volume : total lung capacity are increased. Diffusion capacity of the lung is often reduced. Exercise testing may detect pulmonary dysfunction, even in the early stage of ILD with a decline in oxygen saturation.

Bronchoalveolar Lavage

BAL may provide helpful information regarding secondary infection, bleeding, and aspiration and allows cytology and molecular analyses. Evaluation of cell counts, differential, and lymphocyte markers may be helpful in determining the presence of hypersensitivity pneumonitis or sarcoid. Although BAL does not usually determine the exact diagnosis, it can be diagnostic for disorders such as pulmonary alveolar proteinosis. Lung biopsy for histopathology by conventional thoracotomy or video-assisted thoracoscopy is usually the final step and is often necessary for a diagnosis. Biopsy may have a lower diagnostic yield in young children because of heterogeneous lung changes and often nonspecific histologic findings. Genetic testing for surfactant dysfunction mutational analysis is available. Evaluation for possible systemic disease may also be necessary.

TREATMENT

Supportive care of patients with ILD is essential and includes supplemental oxygen for hypoxia and adequate nutrition for growth failure. Antimicrobial treatment may be necessary for secondary infections. Some children may receive symptomatic relief from the use of bronchodilators. Antiinflammatory treatment with corticosteroids remains the initial treatment of choice. Controlled trials in children are lacking, however, and the clinical responses reported in case studies are variable. The usual dose of prednisone is 1-2 mg/kg/24 hr for 6-8 wks with tapering of dosage dictated by clinical response. Alternative, but not adequately evaluated, agents include hydroxychloroquine, azathioprine, cyclophosphamide, cyclosporine, methotrexate, intravenous immunoglobulin, granulocyte-macrophage colony-stimulating factor, and pulsed high-dose steroids. Investigational approaches involve specific agents directed against the action of cytokines, growth factors, or oxidants. Lung transplantation for progressive or end-stage ILD is successful in some infants and children. Appropriate treatment for underlying systemic disease is indicated. Preventive measures include avoidance of all inhalation irritants, such as tobacco smoke and, when appropriate, molds and bird antigens. Supervised pulmonary rehabilitation programs may be helpful.

Genetic Counseling

A high incidence of ILD in some families suggests a genetic predisposition to either development of the disease or severity of the disorder. Genetic counseling may be beneficial if a positive familial history is obtained.

PROGNOSIS

The overall mortality of ILD is very variable and depends on specific diagnosis. Some children recover spontaneously without treatment, but other children steadily progress to death. Pulmonary hypertension, failure to thrive, and severe fibrosis are considered poor prognostic indicators.

GOODPASTURE DISEASE

Goodpasture disease is the prototypical immunologic mediated interstitial lung disease (see Chapter 517). Because of the concurrent presentation of renal and pulmonary disease, the differential diagnosis focuses on distinguishing Goodpasture disease from GPA, microscopic polyangiitis, Henoch-Schönlein purpura, and idiopathic pulmonary hemorrhage syndromes.

Pathophysiology

Immunology Factors

The development of anti–glomerular basement membrane (anti-GBM) antibodies directly correlates with the development of pulmonary and renal disease. Removal of such antibodies by plasmapheresis results in improvement of the disease process in some patients but not in all. The anti-GBM antibodies are IgG_1 and IgG_4 complement-binding subclasses of IgG which activate complement. Complement fragments signal the recruitment of neutrophils and macrophage in both the lung and kidney basement membranes resulting in damage and capillaritis.

Genetic Factors

Genetics appears to contribute strongly to the development of this disease with the presence of major histocompatibility complex class II alleles DR15, DR4, DRB1*1501, DRB1*04, and DRB1*03 predisposing to disease.

Environmental Factors

Exposure to smoke appears to be a strong factor in the development Goodpasture disease. Whether smoking alters the ultrastructure of the basement membrane or exogenous particles or noxious substances in smoke alter the type IV collagen is unknown. Smokers are more likely to develop pulmonary hemorrhage than non-smokers who have Goodpasture disease. Other injuries to the alveoli from infection, hydrocarbon inhalation, or cocaine inhalation have been reported as associated events prior to development of Goodpasture disease.

Clinical Manifestations

The majority of patients present with many days or weeks of cough, dyspnea, fatigue, and sometimes hemoptysis. Young children tend to swallow small amounts of blood from hemoptysis and may present with vomiting blood. Occasionally, the hemoptysis is large and resultant anemia is a consequence of large quantities of blood loss. Renal compromise is found with abnormal renal function tests. Younger patients tend to present with both the pulmonary and renal syndrome concurrently. Adults are less likely to develop pulmonary disease.

Laboratory

Serologic detection of anti-GBM antibodies are positive in more than 90% of patients with Goodpasture disease. A complete blood count will show anemia that is normocytic and normochromic as seen in chronic inflammatory disease. Urinalysis may reveal hematuria and proteinuria and blood tests demonstrate renal compromise with elevated blood urea nitrogen and creatinine.

Studies for pANCA (antimyeloperoxidase ANCA) should also be performed and are positive in approximately 25-30% of patients concurrently with anti-GBM antibodies. Clinical disease may be more difficult to treat and the presence of these antibodies may herald a more severe form of disease.

Chest Radiography

Chest radiography in Goodpasture disease will often show widely scattered patches of pulmonary infiltrates. If these infiltrates are in the periphery of the lung, they may be difficult to distinguish from the eosinophilic lung diseases. Interstitial patterns of thickening may be found as well. HRCT is usually not performed in this disease as the constellation of pulmonary hemorrhage, renal compromise, and positive serologic tests with anti-GBM antibodies detected often preclude the need for this test.

Pulmonary Function Testing

Pulmonary spirometry often reveals a restrictive defect with reduction in forced vital capacity and forced expiratory volume at 1-second. **DLCO** is a valuable test when pulmonary hemorrhage is a strong consideration. The intent of this test is to measure the ability of the lung to transfer inhaled gas to the red blood cell in the pulmonary capillary bed. This takes advantage of the hemoglobin's high affinity to bind carbon monoxide. It was once thought that reduction of DLCO was a measure of reduced surface area of the alveoli. Current data suggests that it directly correlates with the volume of blood in the pulmonary capillary bed. In pulmonary hemorrhage syndromes, blood in the alveoli plus the blood in the capillary bed increase the DLCO significantly and should alert the clinician to the possibility of pulmonary hemorrhage.

Bronchoscopy and Bronchoalveolar Lavage

Pulmonary abnormalities can often be best assessed by a bronchoscopy with BAL. The visual presence of blood on inspection as well as BAL will be obvious. Infections must be ruled out in many cases, and this technique adds significant value. BAL cell count will show hemosiderin-laden macrophage that have engulfed and broken down the red blood cells, leaving iron in these cells.

Lung Biopsy

Lung biopsy in patients with active disease reveals capillaritis from neutrophils, hemosiderin-laden macrophages, type II pneumocyte hyperplasia, and interstitial thickening at the level of the alveolus. Staining for IgG and complement is found by immunofluorescence in along the basement membrane in a linear pattern. This antibody deposition pattern led to the investigation of endogenous antigens in the basement membrane.

Treatment

More than half of patients with Goodpasture disease who forego treatment die within 2 yr from either respiratory failure, renal failure, or both. After a diagnosis is made, therapy with corticosteroids (e.g., prednisone, 1 mg/kg/day) coupled with oral cyclophosphamide (2.5 mg/kg/day) is begun. The addition of daily plasmapheresis for 2 wks may accelerate improvement. Cyclophosphamide may be discontinued after 2-3 mo. Steroids are often weaned over a 6-9 mo period. Survival is affected by the need for ongoing dialysis. Patients who do not require persistent dialysis have a survival rate at 1 yr of 80% or more.

Chapter 400

Community-Acquired Pneumonia

Matthew S. Kelly and Thomas J. Sandora

EPIDEMIOLOGY

Pneumonia, defined as inflammation of the lung parenchyma, is the leading cause of death globally among children younger than age 5 yr, accounting for an estimated 1.2 million (18% total) deaths annually (Fig. 400-1). The incidence of pneumonia is more than 10-fold higher (0.29 episodes vs 0.03 episodes), and the number of childhood-related deaths from pneumonia ≈2,000 fold higher, in developing than in developed countries (Table 400-1). Fifteen countries account for more than three-fourths of all pediatric deaths from pneumonia.

In the United States from 1939-1996, pneumonia mortality in children declined by 97%; in 1970, pneumonia accounted for 9% of all deaths of children younger than age 5 yr compared to 2% in 2007. It is probable that this decline results from the introduction of antibiotics, vaccines, and the expansion of medical insurance coverage for children. *Haemophilus influenzae* type b (see Chapter 194) was an important cause of bacterial pneumonia in young children but became uncommon with the routine use of effective vaccines, while measles vaccine greatly reduced the incidence of measles-related pneumonia deaths in developing countries. Improved access to healthcare in rural areas of developing countries and the introduction of pneumococcal conjugate vaccines (see Chapter 182) were also important contributors to the further reductions in pneumonia-related deaths achieved over the past decade.

ETIOLOGY

Although most cases of pneumonia are caused by microorganisms, noninfectious causes include aspiration (of food or gastric acid, foreign bodies, hydrocarbons, and lipoid substances), hypersensitivity reactions, and drug- or radiation-induced pneumonitis. The cause of pneumonia in an individual patient is often difficult to determine because direct culture of lung tissue is invasive and rarely performed. Cultures performed on specimens in children obtained from the upper respiratory tract or sputum typically do not accurately reflect the cause of lower respiratory tract infection. With the use of molecular diagnostic testing, a bacterial or viral cause of pneumonia can be identified in

40-80% of children with community-acquired pneumonia. *Streptococcus pneumoniae* (pneumococcus) is the most common bacterial pathogen in children 3 wk to 4 yr of age, whereas *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae* are the most frequent bacterial pathogens in children age 5 yr and older. In addition to pneumococcus, other bacterial causes of pneumonia in previously healthy children in the United States include group A streptococcus (*Streptococcus pyogenes*) and *Staphylococcus aureus* (see Chapter 181.1 and Table 400-2). *S. aureus* pneumonia often complicates an illness caused by influenza viruses.

S. pneumoniae, H. influenzae, and *S. aureus* are the major causes of hospitalization and death from bacterial pneumonia among children in developing countries, although in children with HIV infection, *Mycobacterium tuberculosis* (see Chapter 215), atypical mycobacteria,

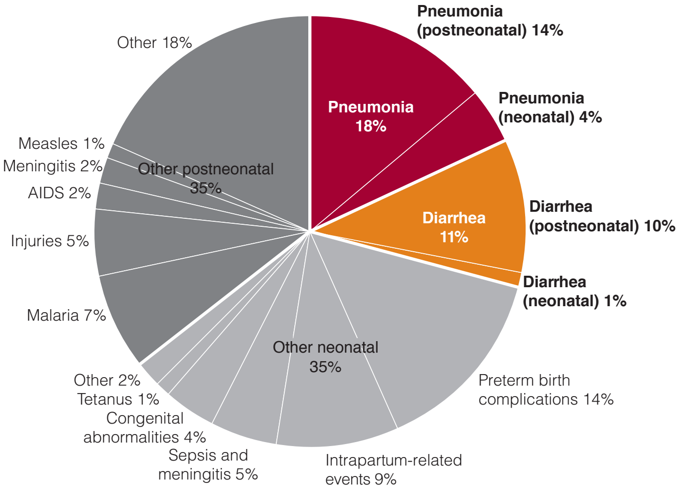

Figure 400-1 Pneumonia is the leading killer of children worldwide, as shown by this illustration of global distribution of cause-specific mortality among children younger than age 5 yr in 2010. Pneumonia causes 18% of all under-5 deaths. Values may not sum to 100% because of rounding. *(From Black RE, Allen LH, Bhutta ZA, et al: Maternal and child undernutrition: global and regional exposures and health consequences.* Lancet *371:243–260, 2008; and Liu L, Johnson HL, Cousens S, et al. Global, regional, and national causes of child mortality: an updated systematic analysis for 2010 with time trends since 2000.* Lancet *379:2151–2161, 2012, Fig. 2.)*

Salmonella (see Chapter 198), *Escherichia coli* (see Chapter 200), and *Pneumocystis jiroveci* (see Chapter 244) must be considered. The incidence of pneumonia caused by *H. influenzae* or *S. pneumoniae* has been significantly reduced in areas where routine immunization has been implemented.

Viral pathogens are a prominent cause of lower respiratory tract infections in infants and children older than 1 mo but younger than 5 yr of age. Viruses can be detected in 40-80% of children with pneumonia using molecular diagnostic methods. Of the respiratory viruses, respiratory syncytial virus (RSV) (see Chapter 260) and rhinoviruses are the most commonly identified pathogens, especially in children younger than 2 yr of age. However, the role of rhinoviruses in severe lower respiratory tract infection remains poorly defined as these viruses are frequently detected in infections with 2 or more pathogens and among asymptomatic children. Other common viruses causing pneumonia include influenza virus (see Chapter 258), parainfluenza viruses, adenoviruses, enteroviruses, and human metapneumovirus. Infection with more than 1 respiratory virus occurs in up to 20% of cases. The age of the patient may help identify possible pathogens (Table 400-3).

Lower respiratory tract viral infections are much more common in the fall and winter in both the northern and southern hemispheres in relation to the seasonal epidemics of respiratory viral infection that occur each year. The typical pattern of these epidemics usually begins in the fall, when parainfluenza infections appear and most often manifest as croup. Later in winter, RSV, human metapneumovirus, and influenza viruses cause widespread infection, including upper respiratory tract infections, bronchiolitis, and pneumonia. RSV is particularly severe among infants and young children, whereas influenza virus causes disease and excess hospitalization for acute respiratory illness in all age groups. Knowledge of the prevailing viral epidemic may lead to a presumptive initial diagnosis.

Immunization status is relevant because children fully immunized against *H. influenzae* type b and *S. pneumoniae* are less likely to be infected with these pathogens. Children who are immunosuppressed or who have an underlying illness may be at risk for specific pathogens, such as *Pseudomonas* spp. in patients with cystic fibrosis (see Chapter 403).

PATHOGENESIS

The lower respiratory tract is normally kept sterile by physiologic defense mechanisms, including mucociliary clearance, the properties of normal secretions such as secretory immunoglobulin (Ig) A, and

Group B streptococci	Neonates
Group A streptococci	Empyema
*Mycoplasma pneumoniae**	Adolescents; summer-fall epidemics
*Chlamydophila pneumoniae**	Adolescents
Chlamydia trachomatis	Infants
Mixed anaerobes	Aspiration pneumonia
Gram-negative enterics	Nosocomial pneumonia
Uncommon	
Haemophilus influenzae type b	Unimmunized
Staphylococcus aureus	Pneumatoceles, empyema; infants
Moraxella catarrhalis	
Neisseria meningitidis	
Francisella tularensis	Animal, tick, fly contact; bioterrorism
Nocardia species	Immunosuppressed persons
*Chlamydophila psittaci**	Bird contact (especially parakeets)
Yersinia pestis	Plague; rat contact; bioterrorism
Legionella species*	Exposure to contaminated water; nosocomial
*Coxiella burnetii**	Q fever; animal (goat, sheep, cattle) exposure
VIRAL	
Common	
Respiratory syncytial virus	Bronchiolitis
Parainfluenza types 1-3	Croup
Influenzas A, B	High fever; winter months
Adenovirus	Can be severe; often occurs between January and April
Human metapneumovirus	Similar to respiratory syncytial virus
Uncommon	
Rhinovirus	Rhinorrhea
Enterovirus	Neonates
Herpes simplex	Neonates
Cytomegalovirus	Infants, immunosuppressed persons
Measles	Rash, coryza, conjunctivitis
Varicella	Adolescents or unimmunized
Hantavirus	Southwestern United States, rodents
Coronavirus (severe acute respiratory syndrome, Middle East respiratory syndrome [MERS])	Asia, Arabian peninsula
FUNGAL	
Histoplasma capsulatum	Ohio/Mississippi River valley; bird, bat contact
Blastomyces dermatitidis	Ohio/Mississippi River valley
Coccidioides immitis	Southwest United States
Cryptococcus neoformans	Bird contact
Aspergillus species	Immunosuppressed persons; nodular lung infection
Mucormycosis	Immunosuppressed persons
Pneumocystis jiroveci	Immunosuppressed, steroids
RICKETTSIAL	
Rickettsia rickettsiae	Tick bite
MYCOBACTERIAL	
Mycobacterium tuberculosis	Travel to endemic region; exposure to high-risk persons
Mycobacterium avium complex	Immunosuppressed persons
PARASITIC	
Various parasites (e.g., Ascaris, *Strongyloides* species)	Eosinophilic pneumonia

*Atypical pneumonia syndrome; may have extrapulmonary manifestations, low-grade fever, patchy diffuse infiltrates, poor response to β-lactam antibiotics, and negative sputum Gram stain.

clearing of the airway by coughing. Immunologic defense mechanisms of the lung that limit invasion by pathogenic organisms include macrophages that are present in alveoli and bronchioles, secretory IgA, and other immunoglobulins. Trauma, anesthesia, and aspiration increase the risk of pulmonary infection.

Viral pneumonia usually results from spread of infection along the airways, accompanied by direct injury of the respiratory epithelium, which results in airway obstruction from swelling, abnormal secretions, and cellular debris. The small caliber of airways in young infants makes such patients particularly susceptible to severe infection. Atelectasis, interstitial edema, and ventilation–perfusion mismatch causing significant hypoxemia often accompany airway obstruction. Viral infection of the respiratory tract can also predispose to secondary bacterial infection by disturbing normal host defense mechanisms, altering secretions, and modifying the bacterial flora.

Bacterial pneumonia most often occurs when respiratory tract organisms colonize the trachea and subsequently gain access to the lungs, but pneumonia may also result from direct seeding of lung tissue after bacteremia. When bacterial infection is established in the lung parenchyma, the pathologic process varies according to the invading organism. *M. pneumoniae* (see Chapter 223) attaches to the respiratory epithelium, inhibits ciliary action, and leads to cellular destruction and an inflammatory response in the submucosa. As the infection progresses, sloughed cellular debris, inflammatory cells, and mucus cause airway obstruction, with spread of infection occurring along the bronchial tree, as it does in viral pneumonia.

S. pneumoniae produces local edema that aids in the proliferation of organisms and their spread into adjacent portions of lung, often resulting in the characteristic focal lobar involvement.

Group A streptococcus infection of the lower respiratory tract results in more diffuse infection with interstitial pneumonia. The pathology includes necrosis of tracheobronchial mucosa; formation of large amounts of exudate, edema, and local hemorrhage, with extension into the interalveolar septa; and involvement of lymphatic vessels and the increased likelihood of pleural involvement.

S. aureus pneumonia manifests in confluent bronchopneumonia, which is often unilateral and characterized by the presence of extensive areas of hemorrhagic necrosis and irregular areas of cavitation of the lung parenchyma, resulting in pneumatoceles, empyema, or, at times, bronchopulmonary fistulas.

From Kliegman RM, Marcdante KJ, Jenson HJ, et al: Nelson essentials of pediatrics, *ed 5, Philadelphia, 2006, Elsevier, p. 507.*

Recurrent pneumonia is defined **as 2 or more** episodes in a single year **or 3 or more** episodes ever, with radiographic clearing between occurrences. An underlying disorder should be considered if a child experiences recurrent pneumonia (Table 400-4).

CLINICAL MANIFESTATIONS

Pneumonia is frequently preceded by several days of symptoms of an upper respiratory tract infection, typically rhinitis and cough. In viral pneumonia, fever is usually present but temperatures are generally lower than in bacterial pneumonia. Tachypnea is the most consistent clinical manifestation of pneumonia. Increased work of breathing accompanied by intercostal, subcostal, and suprasternal retractions, nasal flaring, and use of accessory muscles is common. Severe infection may be accompanied by cyanosis and lethargy, especially in infants. Auscultation of the chest may reveal crackles and wheezing, but it is often difficult to localize the source of these adventitious sounds in very young children with hyperresonant chests. It is often not possible to distinguish viral pneumonia clinically from disease caused by *Mycoplasma* and other bacterial pathogens.

Bacterial pneumonia in adults and older children typically begins suddenly with high fever, cough, and chest pain. Other symptoms that may be seen include drowsiness with intermittent periods of restlessness; rapid respirations; anxiety; and, occasionally, delirium. In many children, splinting on the affected side to minimize pleuritic pain and improve ventilation is noted; such children may lie on one side with the knees drawn up to the chest.

Physical findings depend on the stage of pneumonia. Early in the course of illness, diminished breath sounds, scattered crackles, and rhonchi are commonly heard over the affected lung field. With the development of increasing consolidation or complications of pneumonia such as pleural effusion or empyema, dullness on percussion is noted and breath sounds may be diminished. A lag in respiratory excursion often occurs on the affected side. Abdominal distention may be prominent because of gastric dilation from swallowed air or ileus. *Abdominal pain is common in lower-lobe pneumonia*. The liver may seem enlarged because of downward displacement of the diaphragm secondary to hyperinflation of the lungs or superimposed congestive heart failure.

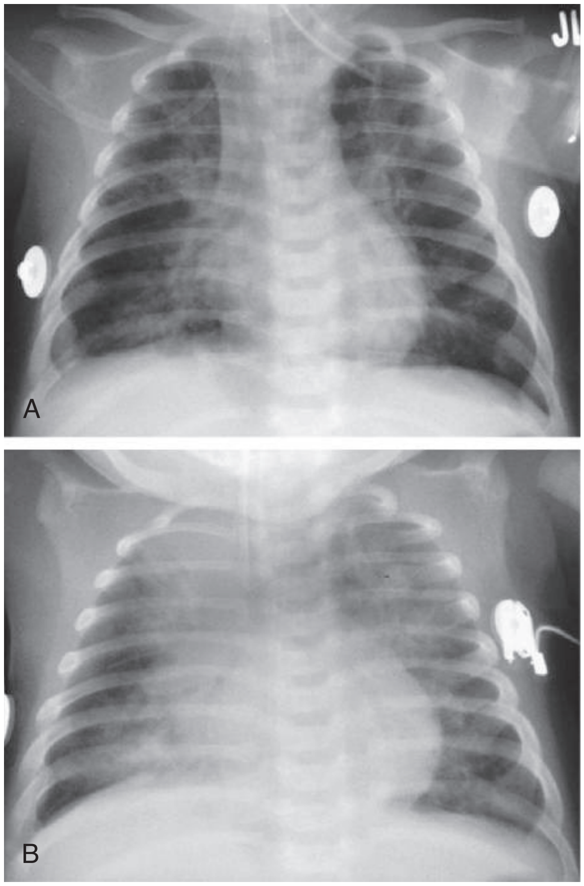

Figure 400-2 A, Radiographic findings characteristic of respiratory syncytial virus pneumonia in a 6 mo old infant with rapid respirations and fever. Anteroposterior radiograph of the chest shows hyperexpansion of the lungs with bilateral fine air space disease and streaks of density, indicating the presence of both pneumonia and atelectasis. An endotracheal tube is in place. **B,** One day later, the anteroposterior radiograph of the chest shows increased bilateral pneumonia.

Symptoms described in adults with pneumococcal pneumonia may be noted in older children but are rarely observed in infants and young children, in whom the clinical pattern is considerably more variable. In infants, there may be a prodrome of upper respiratory tract infection and diminished appetite, leading to the abrupt onset of fever, restlessness, apprehension, and respiratory distress. These infants appear ill, with respiratory distress manifested as grunting; nasal flaring; retractions of the supraclavicular, intercostal, and subcostal areas; tachypnea; tachycardia; air hunger; and often cyanosis. Results of physical examination may be misleading, particularly in young infants, with meager findings disproportionate to the degree of tachypnea. Some infants with bacterial pneumonia may have associated gastrointestinal disturbances characterized by vomiting, anorexia, diarrhea, and abdominal distention secondary to a paralytic ileus. Rapid progression of symptoms is characteristic in the most severe cases of bacterial pneumonia.

DIAGNOSIS

An infiltrate on chest radiograph (posteroanterior **and** lateral views) supports the diagnosis of pneumonia; the film may also indicate a complication such as a pleural effusion or empyema. Viral pneumonia is usually characterized by hyperinflation with bilateral interstitial infiltrates and peribronchial cuffing (Fig. 400-2). Confluent lobar consolidation is typically seen with pneumococcal pneumonia (Fig. 400-3). The radiographic appearance alone is not diagnostic, and other clinical features must be considered. Repeat chest radiographs are not required for proof of cure for patients with uncomplicated pneumonia. Some

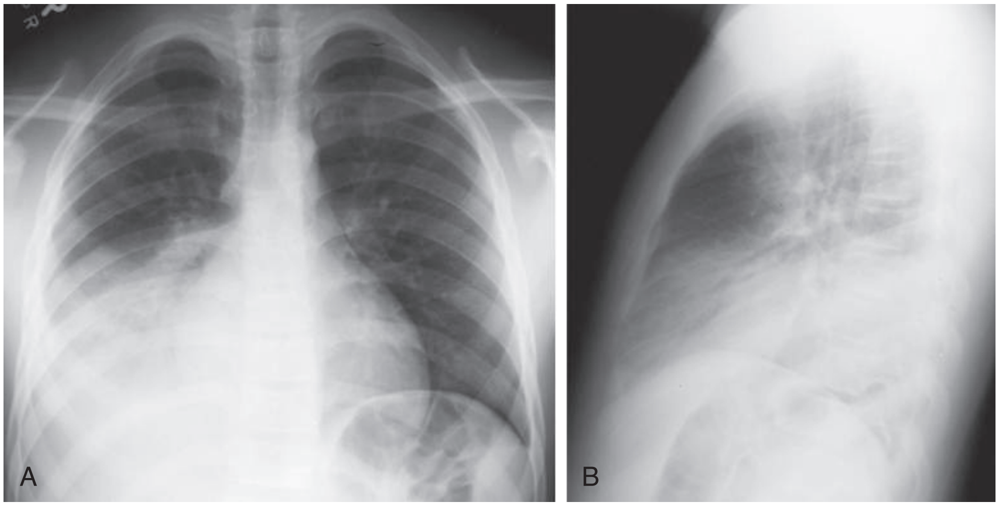

Figure 400-3 Radiographic findings characteristic of pneumococcal pneumonia in a 14 yr old boy with cough and fever. Posteroanterior **(A)** and lateral **(B)** chest radiographs reveal consolidation in the right lower lobe, strongly suggesting bacterial pneumonia.

experts suggest that a chest radiograph may not be necessary for older children with suspected pneumonia (cough, fever, localized crackles, or decreased breath sounds) who are well enough to be managed as outpatients.

Point-of-care use of portable or handheld ultrasonography is highly sensitive and specific in diagnosing pneumonia in children by determining lung consolidations and air bronchograms or effusions.

The peripheral white blood cell (WBC) count can be useful in differentiating viral from bacterial pneumonia. In viral pneumonia, the WBC count can be normal or elevated but is usually not higher than 20,000/mm^3, with a lymphocyte predominance. Bacterial pneumonia is often associated with an elevated WBC count, in the range of 15,000-40,000/mm^3, and a predominance of granulocytes. A large pleural effusion, lobar consolidation, and a high fever at the onset of the illness are also suggestive of a bacterial etiology. **Atypical pneumonia** caused by *C. pneumoniae* or *M. pneumoniae* is difficult to distinguish from pneumococcal pneumonia on the basis of radiographic and laboratory findings, and although pneumococcal pneumonia is associated with a higher WBC count, erythrocyte sedimentation rate, procalcitonin, and C-reactive protein level, there is considerable overlap, particularly with adenoviruses and enteroviruses.

The definitive diagnosis of a viral infection rests on the isolation of a virus or detection of the viral genome or antigen in respiratory tract secretions. Reliable DNA or RNA tests for the rapid detection of many respiratory pathogens, such as mycoplasma, pertussis, and viruses, including RSV, parainfluenza, influenza, and adenoviruses, are available and accurate. Serologic techniques can also be used to diagnose a recent respiratory viral infection but generally require testing of acute and convalescent serum samples for a rise in antibodies to a specific viral agent. This diagnostic technique is laborious, slow, and not generally clinically useful because the infection usually resolves by the time it is confirmed serologically. Serologic testing may be valuable as an epidemiologic tool to define the incidence and prevalence of the various respiratory viral pathogens. Patient peripheral cell gene expression patterns determined by microarray reverse transcription polymerase chain reaction is an emerging technology that may help differentiate viral from bacterial causes of pneumonia.

The definitive diagnosis of a bacterial infection requires isolation of an organism from the blood, pleural fluid, or lung. Culture of sputum is of little value in the diagnosis of pneumonia in young children, while percutaneous lung aspiration is invasive and not routinely performed. Blood culture results are positive in only 10% of children with pneumococcal pneumonia and are not recommended for nontoxic appearing children treated as an outpatient. Blood cultures are recommended for those who fail to improve or have clinical deterioration, in those with complicated pneumonia (Table 400-5) and those requiring hospitalization. Cold agglutinins at titers >1:64 are found in the blood in ≈50% of patients with *M. pneumoniae* infections. Cold agglutinin findings are nonspecific because other pathogens such as influenza viruses may also cause increases. Acute infection caused by *M. pneumoniae* can be diagnosed on the basis of a positive polymerase chain reaction test result or seroconversion in an IgG assay. Serologic evidence, such as the antistreptolysin O titer, may be useful in the diagnosis of group A streptococcal pneumonia.

Table 400-5	Factors Suggesting Need for Hospitalization of Children with Pneumonia
Age <6 mo Sickle cell anemia with acute chest syndrome Multiple lobe involvement Immunocompromised state Toxic appearance Moderate to severe respiratory distress Requirement for supplemental oxygen Complicated pneumonia* Dehydration Vomiting or inability to tolerate oral fluids or medications No response to appropriate oral antibiotic therapy Social factors (e.g., inability of caregivers to administer medications at home or follow-up appropriately)	

*Pleural effusion, empyema, abscess, bronchopleural fistula, necrotizing pneumonia, acute respiratory distress syndrome, extrapulmonary infection (meningitis, arthritis, pericarditis, osteomyelitis, endocarditis), hemolytic uremic syndrome, sepsis.

TREATMENT

Treatment of suspected bacterial pneumonia is based on the presumptive cause and the age and clinical appearance of the child. For mildly ill children who do not require hospitalization, amoxicillin is recommended. With the emergence of penicillin-resistant pneumococci, high doses of amoxicillin (80-90 mg/kg/24 hr) should be prescribed unless local data indicate a low prevalence of resistance. Therapeutic alternatives include cefuroxime axetil and amoxicillin/clavulanate. For school-age children and in children in whom infection with *M. pneumoniae* or *C. pneumoniae* is suggested, a macrolide antibiotic such as

azithromycin is an appropriate choice. In adolescents, a respiratory fluoroquinolone (levofloxacin, moxifloxacin) may be considered as an alternative. Despite substantial gains over the past decade, in developing countries only ≈60% of children with symptoms of pneumonia (≈50% in sub-Saharan Africa) are taken to an appropriate caregiver, and less than one-third receive antibiotics. The World Health Organization and other international groups have developed systems to train mothers and local healthcare providers in the recognition and treatment of pneumonia.

The empiric treatment of suspected bacterial pneumonia in a hospitalized child requires an approach based on the clinical manifestations at the time of presentation. In areas without substantial high-level penicillin resistance among *S. pneumoniae*, children who are fully immunized against *H. influenzae* type b and *S. pneumoniae* and are not severely ill should receive ampicillin or penicillin G. For children who do not meet these criteria, ceftriaxone or cefotaxime should be used. If clinical features suggest staphylococcal pneumonia (pneumatoceles, empyema), initial antimicrobial therapy should also include vancomycin or clindamycin.

If viral pneumonia is suspected, it is reasonable to withhold antibiotic therapy, especially for those patients who are mildly ill, have clinical evidence suggesting viral infection, and are in no respiratory distress. However, up to 30% of patients with known viral infection, particularly influenza viruses, may have coexisting bacterial pathogens. Therefore, if the decision is made to withhold antibiotic therapy on the basis of presumptive diagnosis of a viral infection, deterioration in clinical status should signal the possibility of superimposed bacterial infection, and antibiotic therapy should be initiated.

Table 400-5 notes the indications for admission to a hospital. The optimal duration of antibiotic treatment for pneumonia has not been well-established in controlled studies. However, antibiotics should generally be continued until the patient has been afebrile for 72 hr, and the total duration should not be less than 10 days (or 5 days if azithromycin is used). Shorter courses (5-7 days) may also be effective, particularly for children managed on an outpatient basis, but further study is needed. Available data do not support prolonged courses of treatment for uncomplicated pneumonia. In developing countries, oral zinc (10 mg/day for <12 mo, 20 mg/day for ≥12 mo) reduces mortality among children with clinically defined severe pneumonia.

PROGNOSIS

Typically, patients with uncomplicated community-acquired bacterial pneumonia show response to therapy, with improvement in clinical symptoms (fever, cough, tachypnea, chest pain), within 48-96 hr of initiation of antibiotics. Radiographic evidence of improvement lags substantially behind clinical improvement. A number of possibilities must be considered when a patient does not improve with appropriate antibiotic therapy: (1) complications, such as empyema (see Table 400-5); (2) bacterial resistance; (3) nonbacterial etiologies such as viruses or fungi and aspiration of foreign bodies or food; (4) bronchial obstruction from endobronchial lesions, foreign body, or mucous plugs; (5) preexisting diseases such as immunodeficiencies, ciliary dyskinesia, cystic fibrosis, pulmonary sequestration, or congenital pulmonary airway malformation, formerly called cystic adenomatoid malformation; and (6) other noninfectious causes (including bronchiolitis obliterans, hypersensitivity pneumonitis, eosinophilic pneumonia, aspiration, and granulomatosis with polyangiitis, formerly called Wegener granulomatosis). A repeat chest radiograph is the first step in determining the reason for delay in response to treatment. Bronchoalveolar lavage may be indicated in children with respiratory failure; high-resolution CT scans may better identify complications or an anatomic reason for a poor response to therapy.

Mortality from community-acquired pneumonia in developed nations is rare, and most children with pneumonia do not experience long-term pulmonary sequelae. Some data suggest that up to 45% of children have symptoms of asthma 5 yr after hospitalization for pneumonia; this finding may reflect either undiagnosed asthma at the time of presentation or a propensity for development of asthma after pneumonia.

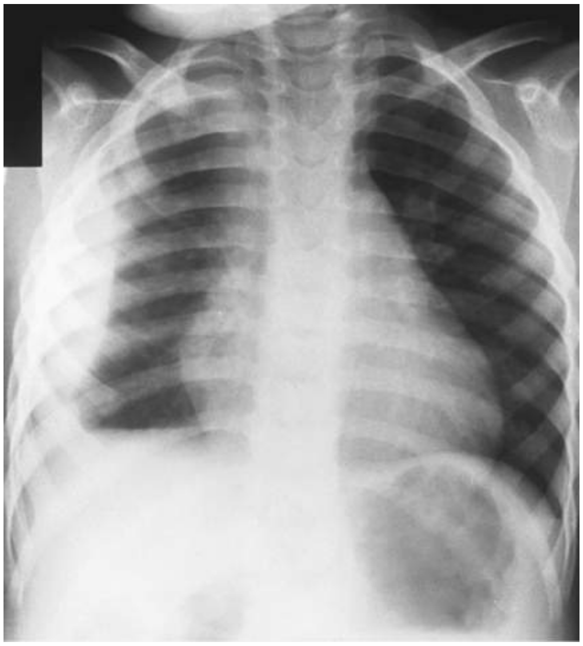

Figure 400-4 **Pneumococcal empyema on the chest radiography of a 3 yr old child who has had upper respiratory symptoms and fever for 3 days.** A pleural fluid collection can be seen on the right side. The patient had a positive pleural tap and blood culture result for pneumococci. The child recovered completely within 3 wk. *(From Kuhn JP, Slovis TL, Haller JO (eds):* Caffrey's pediatric diagnostic imaging, *ed 10, Philadelphia, 2004, Mosby, p. 1002.)*

COMPLICATIONS

Complications of pneumonia (see Table 400-5) are usually the result of direct spread of bacterial infection within the thoracic cavity (pleural effusion, empyema, and pericarditis) or bacteremia and hematologic spread (Fig. 400-4). Meningitis, suppurative arthritis, and osteomyelitis are rare complications of hematologic spread of pneumococcal or *H. influenzae* type b infection.

S. aureus, S. pneumoniae, and *S. pyogenes* are the most common causes of parapneumonic effusions and empyema (Table 400-6). Nonetheless many effusions that complicate bacterial pneumonia are sterile. Universal 16S ribosomal RNA gene polymerase chain reaction identifies the bacterial genome and can determine the bacterial etiology of the effusion if the culture is negative. The treatment of empyema is based on the stage (exudative, fibrinopurulent, organizing). Imaging studies including ultrasonography and CT are helpful in determining the stage of empyema. The mainstays of therapy include antibiotic therapy and drainage with tube thoracostomy. Additional effective approaches include the use of intrapleural fibrinolytic therapy (urokinase, streptokinase, tissue plasminogen activator) and selected video-assisted thoracoscopy to debride or lyse adhesions and drain loculated areas of pus. Early diagnosis and intervention, particularly with fibrinolysis or less often video-assisted thoracoscopy, may obviate the need for thoracotomy and open debridement. Fibrinolysis is more cost-effective than video-assisted thoracoscopy.

PREVENTION

Some evidence exists to suggest that vaccination has reduced the incidence of pneumonia hospitalizations. The annual rate of all-cause pneumonia hospitalization among children younger than 2 yr of age in the United States during the period 1997-1999 was 12.5 per 1,000 children. In February 2000, the 7-valent pneumococcal conjugate vaccine (PCV7) was licensed and recommended. In 2006, the pneumonia hospitalization rate in this age group was 8.1 per 1,000 children, a 35% decrease from the prevaccine rate. Although these data do not establish that PCV7 directly reduced pneumonia hospitalization rates,

Table 400-6 Differentiation of Pleural Fluid		
	TRANSUDATE	**EMPYEMA**
Appearance	Clear	Cloudy or purulent
Cell count (per mm^3)	<1,000	Often >50,000 (cell count has limited predictive value)
Cell type	Lymphocytes, monocytes	Polymorphonuclear leukocytes (neutrophils)
Lactate dehydrogenase	<200 U/L	More than two-thirds upper limit of normal for serum lactate dehydrogenase (LDH)
Pleural fluid : serum LDH ratio	<0.6	>0.6
Protein >3 g	Unusual	Common
Pleural fluid : serum protein ratio	<0.5	>0.5
Glucose*	Normal	Low (<40 mg/dL)
pH*	Normal (7.40-7.60)	<7.10
Gram stain	Negative	Occasionally positive (less than one-third of cases)
Cholesterol		>55 mg/dL
Pleural cholesterol : serum cholesterol ratio	<0.3	>0.3

*Low glucose or pH may be seen in malignant effusion, tuberculosis, esophageal rupture, pancreatitis (positive pleural amylase), and rheumatologic diseases (e.g., systemic lupus erythematosus).

From Kliegman RM, Greenbaum LA, Lye PS: Practical strategies in pediatric diagnosis & therapy, *ed 2, Philadelphia, 2004, Elsevier, p. 30.*

they do suggest that vaccination has resulted in a sustained benefit in preventing hospitalization for young children with pneumonia.

In 2010, the 13-valent pneumococcal conjugate vaccine (PCV13) was licensed in the United States; it may prevent even more cases of pneumococcal disease not covered by the PCV7 vaccine.

The expansion of influenza vaccine recommendations to include all children >6 mo of age in 2010 might be expected to affect pneumonia hospitalization rates in a similar fashion, and ongoing surveillance is warranted.

Chapter 401
Bronchiectasis
Oren J. Lakser

Bronchiectasis is characterized by irreversible abnormal dilation and anatomic distortion of the bronchial tree and represents a common end stage of a many nonspecific and unrelated antecedent events. Its incidence has been decreasing overall in industrialized countries, but it persists as a problem in lower and middle income countries and among some ethnic groups in industrialized nations. Females are afflicted more frequently than males.

PATHOPHYSIOLOGY AND PATHOGENESIS

In industrialized nations, cystic fibrosis (see Chapter 403) is the most common cause of clinically significant bronchiectasis. Other conditions associated with bronchiectasis include primary ciliary dyskinesia (see Chapter 404), foreign-body aspiration (see Chapter 387), aspiration of gastric contents, immune deficiency syndromes (especially humoral immunity), and infection, especially pertussis, measles, and tuberculosis (Table 401-1). Bronchiectasis can also be congenital, as in **Williams-Campbell syndrome**, in which there is an absence of annular bronchial cartilage, and **Marnier-Kuhn syndrome** (congenital tracheobronchomegaly), in which there is a connective tissue disorder. Other disease entities associated with bronchiectasis are **right middle lobe syndrome** (chronic extrinsic compression of right middle lobe bronchus by hilar lymph nodes) and **yellow nail syndrome** (pleural effusion, lymphedema, discolored nails).

Three basic mechanisms are involved in the pathogenesis of bronchiectasis. Obstruction can occur because of tumor, foreign body, impacted mucus because of poor mucociliary clearance, external

compression, bronchial webs, and atresia. Infections caused by *Bordetella pertussis*, measles, rubella, togavirus, respiratory syncytial virus, adenovirus, and *Mycobacterium tuberculosis* induce chronic inflammation, progressive bronchial wall damage, and dilation. Chronic inflammation similarly contributes to the mechanism by which obstruction leads to bronchiectasis. Activation of toll-like receptors results in the activation of nuclear factor κβ and the release of proinflammatory cytokines interleukin (IL)-1β, IL-8, and tumor necrosis factor-α. IL-8 is a chemoattractant for neutrophils, which are the main inflammatory cell involved in the pathogenesis of bronchiectasis. Once activated neutrophils produce neutrophil elastase and matrix metalloproteinases, MMP-8 and MMP-9. IL-6, IL-8, and tumor necrosis factor-α are elevated in the airways of patients with bronchiectasis. The mechanism by which bronchiectasis occurs in congenital forms is likely related to abnormal cartilage formation. The common thread in the pathogenesis of bronchiectasis consists of difficulty clearing secretions and recurrent infections with a "vicious cycle" of infection and inflammation resulting in airway injury and remodeling.

Bronchiectasis can manifest in any combination of three pathologic forms, best defined by high-resolution CT (HRCT) scan. In cylindrical bronchiectasis, the bronchial outlines are regular, but there is diffuse dilation of the bronchial unit. The bronchial lumen ends abruptly because of mucous plugging. In varicose bronchiectasis, the degree of dilation is greater, and local constrictions cause an irregularity of outline resembling that of varicose veins. There may also be small sacculations. In saccular (cystic) bronchiectasis, bronchial dilation progresses and results in ballooning of bronchi that end in fluid- or mucus-filled sacs. This is the most severe form of bronchiectasis. Bronchiectasis lies within a disease spectrum of chronic pediatric suppurative lung disease. The following definitions have been proposed: **prebronchiectasis** (chronic or recurrent endobronchial infection with nonspecific HRCT changes; may be reversible); **HRCT bronchiectasis** (clinical symptoms with HRCT evidence of bronchial dilation; may persist, progress, or improve and resolve); **established bronchiectasis** (like the previous but with no resolution within 2 yr). Early diagnosis and aggressive therapy are important to prevent the development of established bronchiectasis.

CLINICAL MANIFESTATIONS

The most common complaints in patients with bronchiectasis are cough and production of copious purulent sputum. Younger children may swallow the sputum. Hemoptysis is seen with some frequency. Fever can occur with infectious exacerbations. Anorexia and poor weight gain may occur as time passes. Physical examination typically reveals crackles localized to the affected area, but wheezing as well as digital clubbing may also occur. In severe cases, dyspnea and hypoxemia can occur. Pulmonary function studies may demonstrate an obstructive, restrictive, or mixed pattern. Typically, impaired diffusion capacity is a late finding.

DIAGNOSIS

Conditions that can be associated with bronchiectasis should be ruled out by appropriate investigations (e.g., sweat test, immunologic work-up). Chest radiographs of patients with bronchiectasis tend to be nonspecific. Typical findings can include increase in size and loss of definition of bronchovascular markings, crowding of bronchi, and loss of lung volume. In more severe forms, cystic spaces, occasionally with air–fluid levels and honeycombing, may occur. Compensatory overinflation of unaffected lung may be seen. Thin-section HRCT scanning is the gold standard, because it has excellent sensitivity and specificity. CT provides further information on disease location, presence of mediastinal lesions, and the extent of segmental involvement. The addition of radiolabeled aerosol inhalation to CT scanning can provide even more information. The CT findings in patients with bronchiectasis typically include cylindrical ("tram lines," "signet ring appearance"), varicose (bronchi with "beaded contour"), cystic (cysts in "strings and clusters"), or mixed forms (Fig. 401-1). The lower lobes are most commonly affected.

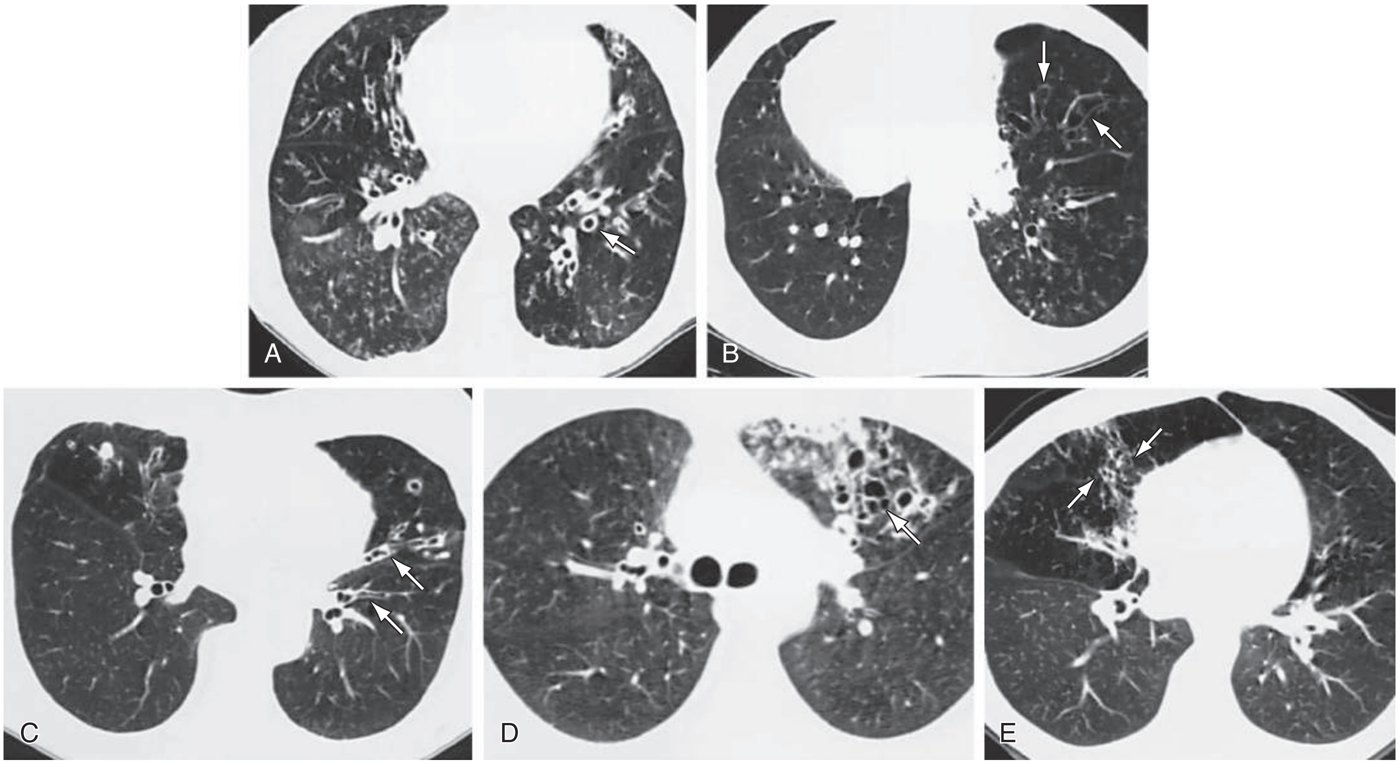

Figure 401-1 High-resolution CT scans of lungs with bronchiectasis. **A,** Dilated and thickened airways *(arrow)*. **B,** Airways do not taper *(arrows)* toward the periphery in a patient with Kartagener syndrome. **C,** Varicose changes (dilated and beaded airways *[arrows]*). **D,** Clustered cysts or saccules *(arrow)* as well as a peripheral infiltrate. **E,** Middle lobe bronchiectasis *(arrows)* in a patient with *Mycobacterium avium* complex infection. *(From Barker AF: Bronchiectasis,* N Engl J Med *346:1383, 2002.)*

TREATMENT

The initial therapy for patients with bronchiectasis is medical and aims at decreasing airway obstruction and controlling infection. Chest physiotherapy (postural drainage), antibiotics, and bronchodilators are essential. Two to 4 wk of parenteral antibiotics is often necessary to manage acute exacerbations adequately. Exacerbations can be defined as the presence of 1 major criteria (wet cough enduring longer than 72 hr, increased cough frequency over 72 hr) *plus* 1 laboratory criteria (C-reactive protein >3 mg/L, serum IL-6 >2 ng/L, serum amyloid A >5 mg/L, elevated neutrophil percentage), 2 major criteria, or 1 major criteria *plus* 2 minor criteria (change in sputum color, breathlessness, chest pain, crackles/crepitations, wheeze). Antibiotic choice is dictated by the identification and sensitivity of organisms found on deep throat, sputum (induced or spontaneous), or bronchoalveolar lavage fluid cultures. The most common organisms found in children with bronchiectasis include *Streptococcus pneumoniae*, *Haemophilus influenzae* non-type b, *Moraxella catarrhalis*, and *Mycoplasma pneumoniae*. Amoxicillin/clavulanic acid (22.5 mg/kg/dose twice daily) has been particularly successful at treating most pulmonary exacerbations. Long-term prophylactic oral (macrolide) or nebulized antibiotics (e.g., tobramycin, colistin, aztreonam) may be beneficial. Airway hydration (inhaled hypertonic saline or mannitol) also improves quality of life in adults with bronchiectasis. Any underlying disorder (immunodeficiency, aspiration) that may be contributing must be addressed. When localized bronchiectasis becomes more severe or resistant to medical management, segmental or lobar resection may be warranted. Lung transplantation can also be performed in patients with bronchiectasis. A review of randomized trials among adult patients with bronchiectasis did not find strong evidence to support the routine use of inhaled corticosteroids, although some studies demonstrate improved quality of life and reduced exacerbations in patients with bronchiectasis treated with inhaled corticosteroids. Although preventative strategies, including immunization against typical respiratory pathogens (influenza, pneumococci), are generally recommended, no studies have been conducted to date to address the efficacy of these recommendations.

PROGNOSIS

Children with bronchiectasis often suffer from recurrent pulmonary illnesses, resulting in missed school days, stunted growth, osteopenia, and osteoporosis. The prognosis for patients with bronchiectasis has improved considerably in the past few decades. Earlier recognition or prevention of predisposing conditions, more powerful and broad-spectrum antibiotics, and improved surgical outcomes are likely reasons.

Chapter 402
Pulmonary Abscess
Oren J. Lakser

Lung infection that destroys the lung parenchyma, resulting in cavitations and central necrosis, can result in localized areas composed of thick-walled purulent material, called **lung abscesses**. **Primary lung abscesses** occur in previously healthy patients with no underlying medical disorders and are usually solitary. **Secondary lung abscesses** occur in patients with underlying or predisposing conditions and may be multiple. Lung abscesses are much less common in children (estimated at 0.7 per 100,000 admissions per year) than in adults.

PATHOLOGY AND PATHOGENESIS
A number of conditions predispose children to the development of pulmonary abscesses, including aspiration, pneumonia, cystic fibrosis (see Chapter 403), gastroesophageal reflux (see Chapter 323), tracheoesophageal fistula (see Chapter 319), immunodeficiencies, postoperative complications of tonsillectomy and adenoidectomy, seizures, a variety of neurologic diseases, and other conditions associated with impaired mucociliary defense. In children, aspiration of infected materials or a foreign body is the predominant source of the organisms causing abscesses. Initially, pneumonitis impairs drainage of fluid or the aspirated material. Inflammatory vascular obstruction occurs, leading to tissue necrosis, liquefaction, and abscess formation. Abscess can also occur as a result of pneumonia and hematogenous seeding from another site.

If the aspiration event occurred while the child was recumbent, the right and left upper lobes and apical segment of the right lower lobes are the dependent areas most likely to be affected. In a child who was upright, the posterior segments of the upper lobes were dependent and therefore are most likely to be affected. Primary abscesses are found most often on the right side, whereas secondary lung abscesses, particularly in immunocompromised patients, have a predilection for the left side.

Both anaerobic and aerobic organisms can cause lung abscesses. Common anaerobic bacteria that can cause a pulmonary abscess include *Bacteroides* spp., *Fusobacterium* spp., and *Peptostreptococcus* spp. Abscesses can be caused by aerobic organisms such as *Streptococcus* spp., *Staphylococcus aureus, Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa,* and very rarely *Mycoplasma pneumoniae.* Aerobic and anaerobic cultures should be part of the work-up for all patients with lung abscess. Occasionally, concomitant viral–bacterial infection can be detected. Fungi can also cause lung abscesses, particularly in immunocompromised patients.

CLINICAL MANIFESTATIONS
The most common symptoms of pulmonary abscess in the pediatric population are cough, fever, tachypnea, dyspnea, chest pain, vomiting, sputum production, weight loss, and hemoptysis. Physical examination typically reveals tachypnea, dyspnea, retractions with accessory muscle use, decreased breath sounds, and dullness to percussion in the affected area. Crackles and, occasionally, a prolonged expiratory phase may be heard on lung examination.

DIAGNOSIS
Diagnosis is most commonly made on the basis of chest radiography. Classically, the chest radiograph shows a parenchymal inflammation with a cavity containing an air–fluid level (Fig. 402-1). A chest CT scan can provide better anatomic definition of an abscess, including location and size (Fig. 402-2).

An abscess is usually a thick-walled lesion with a low-density center progressing to an air–fluid level. Abscesses should be distinguished from pneumatoceles, which often complicate severe bacterial pneumonias and are characterized by thin- and smooth-walled, localized air collections with or without air–fluid level (Fig. 402-3). Pneumatoceles often resolve spontaneously with the treatment of the specific cause of the pneumonia.

The determination of the etiologic bacteria in a lung abscess can be very helpful in guiding antibiotic choice. Although Gram stain of sputum can provide an early clue as to the class of bacteria involved, sputum cultures typically yield mixed bacteria, and therefore are not always reliable. Attempts to avoid contamination from oral flora include direct lung puncture, percutaneous (aided by CT guidance) or transtracheal aspiration, and bronchoalveolar lavage specimens obtained bronchoscopically. Bronchoscopic aspiration should be avoided as it can be complicated by massive intrabronchial aspiration, and great care should therefore be taken during the procedure. To avoid invasive procedures in previously normal hosts, empiric therapy can be initiated in the absence of culturable material.

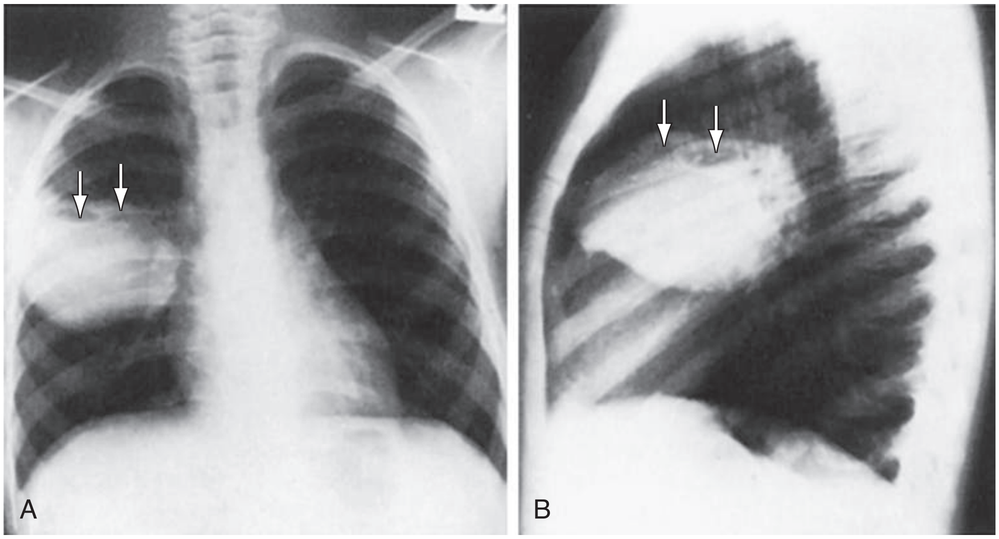

Figure 402-1 **A** and **B,** Multiloculated lung abscess *(arrows). (From Brook I: Lung abscess and pulmonary infections due to anaerobic bacteria. In Chernick V, Boat TF, Wilmott RW, et al, editors:* Kendig's disorders of the respiratory tract in children, *ed 7, Philadelphia, 2006, WB Saunders, p. 482.)*

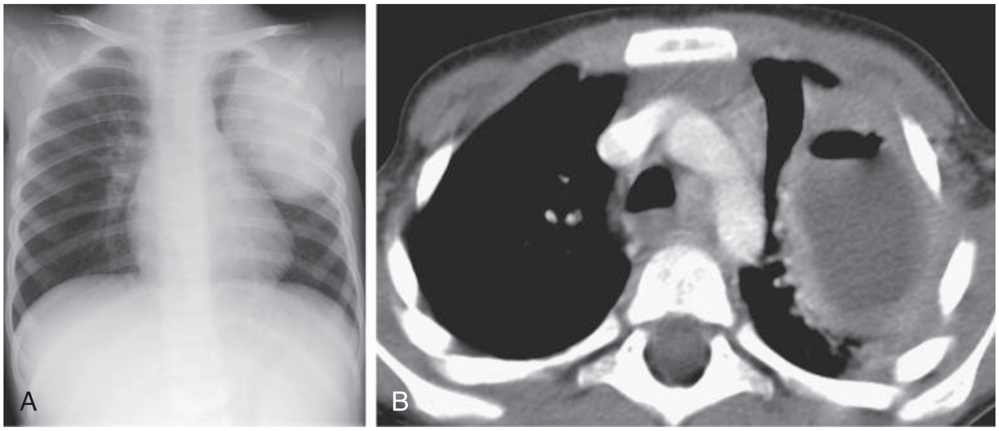

Figure 402-2 Pulmonary abscess in a 2 yr old boy with persistent cough. **A,** Chest radiograph shows large oval mass in the left upper lobe. **B,** CT scan demonstrates an abscess with a thick enhancing wall that contains both air and fluid. *(From Slovis TL, editor:* Caffey's pediatric diagnostic imaging, *ed 11, Philadelphia, 2008, Mosby, Fig. 78-3, p. 1297.)*

TREATMENT

Conservative management is recommended for pulmonary abscess. Most experts advocate a 2-3 wk course of parenteral antibiotics for uncomplicated cases, followed by a course of oral antibiotics to complete a total of 4-6 wk. Antibiotic choice should be guided by results of Gram stain and culture but initially should include agents with aerobic and anaerobic coverage. Treatment regimens should include a penicillinase-resistant agent active against *S. aureus* and anaerobic coverage, typically with clindamycin or ticarcillin/clavulanic acid. If Gram-negative bacteria are suspected or isolated, an aminoglycoside should be added. Early CT-guided percutaneous aspiration or drainage has been advocated as it can hasten the recovery and shorten the course of parenteral antibiotic therapy needed.

For severely ill patients or those whose status fails to improve after 7-10 days of appropriate antimicrobial therapy, surgical intervention should be considered. Minimally invasive percutaneous aspiration techniques, often with CT guidance, are the initial and, often, only intervention required. Thoracoscopic drainage has also been successfully utilized with minimal complications. In rare complicated cases, thoracotomy with surgical drainage or lobectomy and/or decortication may be necessary.

PROGNOSIS

Overall, prognosis for children with primary pulmonary abscesses is excellent. The presence of aerobic organisms may be a negative prognostic indicator, particularly in those with secondary lung abscesses. Most children become asymptomatic within 7-10 days, although the fever can persist for as long as 3 wk. Radiologic abnormalities usually resolve in 1-3 mo but can persist for years.

Chapter 403

Cystic Fibrosis

Marie E. Egan, Deanna M. Green, and Judith A. Voynow

Cystic fibrosis (CF) is an inherited multisystem disorder of children and adults; it is the most common life-limiting recessive genetic trait among whites. Dysfunction of the *cystic fibrosis transmembrane conductance regulator protein* (CFTR), the primary defect, leads to a wide and variable array of presenting manifestations and complications.

CF is responsible for most cases of exocrine pancreatic insufficiency in early life and is the major cause of severe chronic lung disease in children. It is also responsible for many cases of hyponatremic salt depletion, nasal polyposis, pansinusitis, rectal prolapse, pancreatitis, cholelithiasis, and nonautoimmune insulin-dependent hyperglycemia. Because CF may manifest as failure to thrive and, occasionally, as cirrhosis or other forms of hepatic dysfunction, this disorder enters into the differential diagnosis of many pediatric conditions (Table 403-1).

GENETICS

CF occurs most frequently in white populations of northern Europe, North America, and Australia/New Zealand. The prevalence in these populations varies but approximates 1 in 3,500 live births (1 in 9,200 individuals of Hispanic descent and 1 in 15,000 African-Americans). Although less frequent in African, Hispanic, Middle Eastern, South Asian, and eastern Asian populations, the disorder does exist in these populations as well (Fig. 403-1).

CF is inherited as an autosomal recessive trait. The CF gene codes for the CFTR protein, which is 1,480 amino acids. CFTR is expressed largely in epithelial cells of airways, the gastrointestinal tract (including the pancreas and biliary system), the sweat glands, and the genitourinary system. CFTR is a member of the adenosine triphosphate–binding cassette superfamily of proteins. It functions as a chloride channel and has other regulatory functions that are perturbed variably by the different mutations. More than 1,900 *CFTR* polymorphisms grouped into 5 main classes of mutations that affect protein function are associated with the CF syndrome (Table 403-2). The most prevalent mutation of *CFTR* is the deletion of a single phenylalanine residue at amino acid 508 (F508del). This mutation is responsible for the high incidence of CF in northern European populations and is considerably less frequent in other populations, such as those of southern Europe and Israel. Approximately 50% of individuals with CF who are of northern European ancestry are homozygous for F508del, and more than 80% carry at least 1 F508del gene. Remaining patients have an extensive array of mutations, none of which has a prevalence of more than several percentage points, except in certain populations; for example, the W1282X mutation occurs in 60% of Ashkenazi Jews with CF. The relationship between CFTR genotype and clinical phenotype is

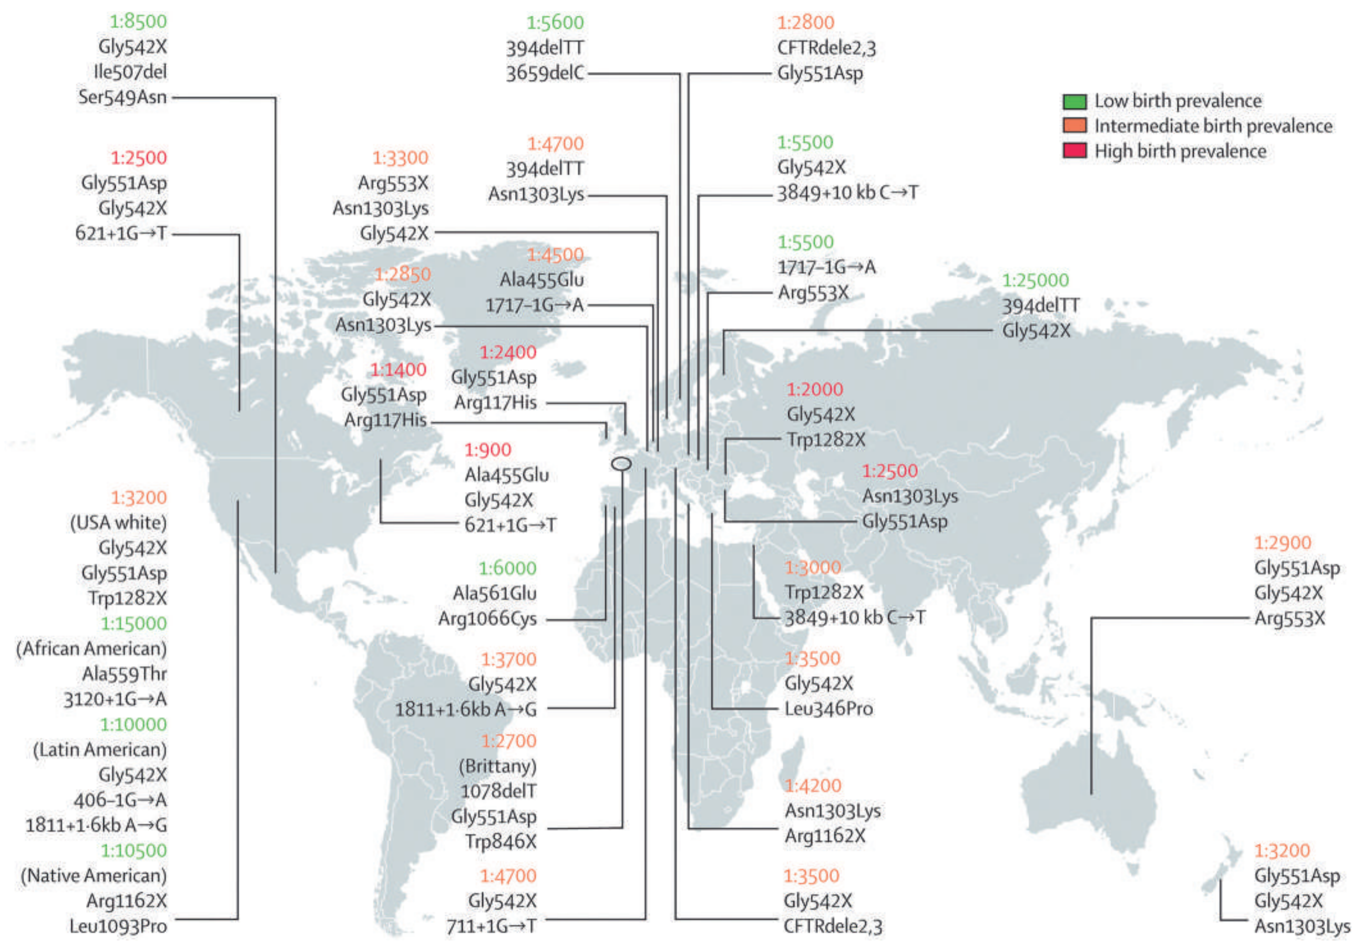

Figure 403-1 **Approximate cystic fibrosis birth prevalence and common mutations for selected countries.** Birth prevalence is reported as number of live births per case of cystic fibrosis. Common/important mutations in each region are listed below the prevalence figures. The birth prevalence can vary greatly among ethnic groups in a country. *(From O'Sullivan BP, Freedman SD: Cystic fibrosis,* Lancet *373:1891–1902, 2009.)*

Table 403-2 One Proposed Classification of Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) Mutations

CLASS	EFFECT ON CFTR	FUNCTIONAL CFTR PRESENT?	SAMPLE MUTATIONS
I	Lack of protein production	No	Stop codons (designation in X; e.g., Trp1282X, Gly542X); splicing defects with no protein production (e.g., 711+1G→T, 1717-1G→A)
II	Defect in protein trafficking with ubiquitination and degradation in endoplasmic reticulum/Golgi body	No/substantially reduced	Phe508del, Asn1303Lys, Gly85Gly, leu1065Pro, Asp507, Ser549Arg
III	Defective regulation; CFTR not activated by adenosine triphosphate or cyclic adenosine monophosphate	No (nonfunction CFTR present in apical membrane)	Gly551Asp, Ser492Phe, Val520Phe, Arg553Gly, Arg560Thr, Arg560Ser
IV	Reduced chloride transport through CFTR at the apical membrane	Yes	Ala455Glu, Arg117Cys, Asp1152His, Leu227Arg, Arg334Trp, Arg117His*
V	Splicing defect with reduced production of CFTR	Yes	3849+10kbC→T, 1811+16kbA→G, IVS8-5T, 2789+5G→A

*Function of Arg117His depends on the length of the polythymidine track on the same chromosome in intron 8 (IVS8): 5T, 7T, or 9T. There is more normal CFTR function with a longer polythymidine track.

From O'Sullivan BP, Freedman SD: Cystic fibrosis, Lancet *373:1891–1902, 2009.*

highly complex and is not predictable for individual patients. Mutations categorized as "severe" are associated almost uniformly with pancreatic insufficiency but only in general with more rapid progression of lung disease. *A few mutations, such as 3849 + 10kbC→T, are found in patients with normal sweat chloride concentrations.* Some individuals with polymorphisms of both *CFTR* genes have few or no CF manifestations until adolescence or adulthood, when they present with pancreatitis, sinusitis, diffuse bronchiectasis, or male infertility. Whereas *CFTR* mutations are a sine qua non for CF, 2 mutations of *CFTR* can cause disorders that do not meet diagnostic criteria for CF and, occasionally, do not cause discernible clinical problems. Non-CFTR modifier gene polymorphisms appear to be responsible for

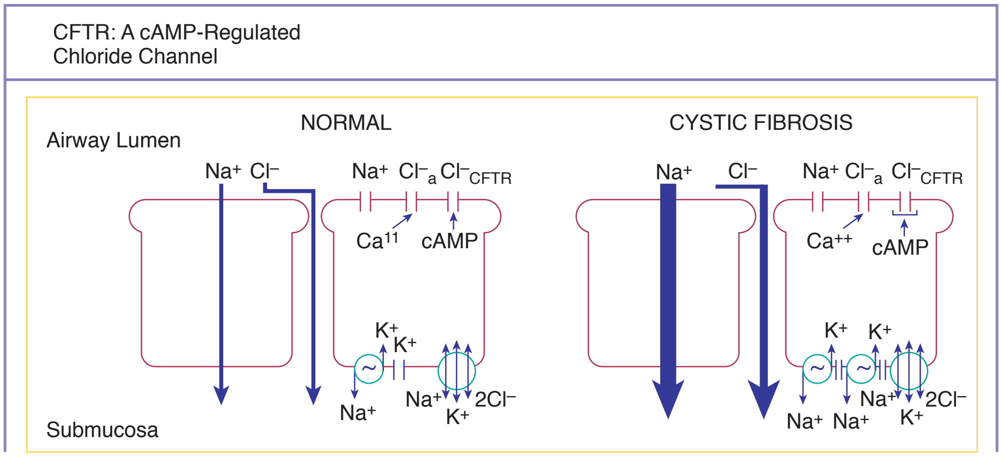

Figure 403-2 The net ion flow across normal and cystic fibrosis (CF) airway epithelia under basal conditions *(large arrows).* Because water follows salt movement, the predicted net flux of water would be from the airway lumen to the submucosa and would be greater across CF epithelia. The increased Na^+ absorption by CF cells is associated with an increased amiloride-sensitive Na^+ conductance across the apical (luminal) membrane and increased Na^+,K^+-adenosine triphosphatase (ATPase) sites at the basolateral membrane. The cyclic adenosine monophosphate (cAMP)–mediated apical membrane conductance of Cl^- associated with the CF transmembrane regulator (CFTR) does not function in CF epithelia, but an alternative, calcium (Ca^{++})–activated Cl^- conductance is present in normal and CF cells. It is postulated that CF cells have a limited ability to secrete Cl^- and absorb Na+ in excessive amounts, limiting the water available to hydrate secretions and allow them to be cleared from the airways lumen. Cl^-a, Ca^{++}–activated Cl^- conductance: Cl^-CTFR, the CFTR Cl^- channel. *(From Knowles MR: Contemporary perspectives on the pathogenesis of cystic fibrosis,* New Insights Cystic Fibrosis *1:1, 1993.)*

much of the variation in the progression of lung disease. Genomewide association studies provide an unbiased approach to test for novel polymorphisms that associate with CF lung disease severity. Genomewide association studies identified a polymorphism on chromosome 11 in the intergenic region between EHF (an epithelial transcription factor) and APIP (an inhibitor of apoptosis) that is associated with lung disease severity, and may influence the expression of *EHF* and *APIP*, as well as other genes in the region, including *PDHX*, *CD44*, and *ELF5*. A region on chromosome 20 was also found to relate to lung disease severity. This region encompasses several genes (*MC3R*, *CASS4*, *AURKA*) that may play a role in lung host-defense involving neutrophil function, apoptosis, and phagocytosis. Genomewide association studies analysis also identified genetic regions that predispose to risk for liver disease, CF-related diabetes, and meconium ileus.

Through the use of probes for 40 of the most common mutations, the genotype of 80-90% of Americans with CF can be ascertained. Genotyping using a discreet panel of mutation probes is quick and less costly than more comprehensive sequencing and is commercially available. In special cases, sequencing the entire *CFTR* gene is necessary to establish the genotype. This procedure is also available commercially and can identify polymorphisms and unique mutations of unknown clinical importance.

The high frequency of *CFTR* mutations has been ascribed to resistance to the morbidity and mortality associated with infectious dysenteries through the ages. In support of this hypothesis, cultured CF intestinal epithelial cells homozygous for the F508del mutation are unresponsive to the secretory effects of cholera toxin. CFTR heterozygous mice experience less mortality when treated with cholera toxin than their unaffected wild type littermates.

PATHOGENESIS

A number of long-standing observations of CF are of fundamental pathophysiologic importance; they include failure to clear mucous secretions, a paucity of water in mucous secretions, an elevated salt content of sweat and other serous secretions, and chronic infection limited to the respiratory tract. Additionally, there is a greater negative potential difference across the respiratory epithelia of patients with CF than across the respiratory epithelia of control subjects. Aberrant electrical properties are also demonstrated for CF sweat gland duct and rectal epithelia. The membranes of CF epithelial cells are unable to secrete chloride ions in response to cyclic adenosine monophosphate–mediated signals, and at least in the respiratory tract, excessive amounts of sodium are absorbed through these membranes (Fig. 403-2). These defects can be traced to a dysfunction of CFTR (Figs. 403-3 and 403-4).

Cyclic adenosine monophosphate–stimulated protein kinase A regulation of chloride conductance is the primary function of CFTR; this function is absent in epithelial cells with many different mutations of the *CFTR* gene. *CFTR* mutations fall into 5 classes in another classification system, albeit with some overlap (see Fig. 403-4). Individuals with classes I, II, and III mutations, on average, have shorter survival than those with "mild" genotypes (class IV or V). The clinical importance of these functional categories is limited because they do not uniformly correlate with specific clinical features or their severity. Rather, clinical features correlate with the residual CFTR activity.

Many hypotheses have been postulated to explain how CFTR dysfunction results in the clinical phenotype. It is likely that no one hypothesis explains the full spectrum of disease. Most believe that the epithelial pathophysiology in airways involves an inability to secrete salt and secondarily to secrete water in the presence of excessive reabsorption of salt and water. The proposed outcome is insufficient water on the airway surface to hydrate secretions. Desiccated secretions become more viscous and elastic (rubbery) and are harder to clear by mucociliary and other mechanisms. In addition it has been suggested that CFTR dysfunction results in an altered microenvironment with low HCO_3^- and a more acidic pH, thus altering mucus rheology and aggravating poor mucociliary clearance. The result is that these secretions are retained and obstruct airways, starting with those of the smallest caliber, the bronchioles. Airflow obstruction at the level of small airways is the earliest observable physiologic abnormality of the respiratory system.

It is plausible that similar pathophysiologic events take place in the pancreatic and biliary ducts (and in the vas deferens), leading to desiccation of proteinaceous secretions and obstruction. Because the function of sweat gland duct cells is to absorb rather than secrete chloride, salt is not retrieved from the isotonic primary sweat as it is transported to the skin surface; chloride and sodium levels are consequently elevated.

Chronic infection in CF is limited to the airways. A likely explanation for infection is a sequence of events starting with failure to clear inhaled bacteria promptly and then proceeding to persistent colonization and an inflammatory response in airway walls. In addition, it has

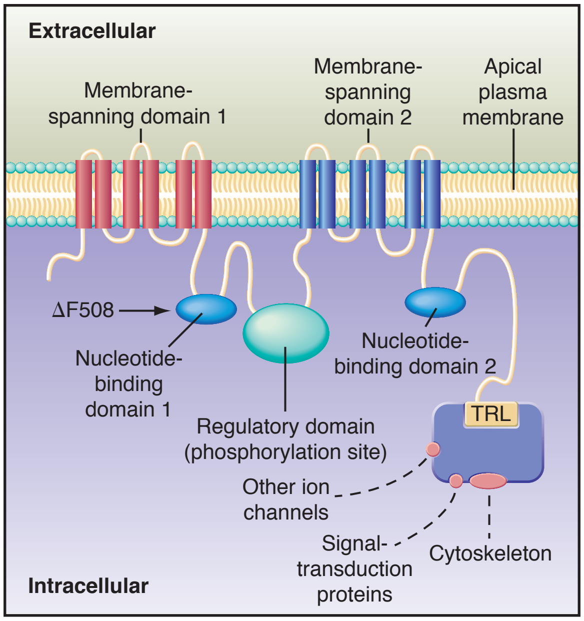

Figure 403-3 **Hypothesized structure of cystic fibrosis transmembrane regulator (CFTR).** The protein contains 1,480 amino acids and a number of discrete globular and transmembrane domains. Activation of CFTR relies on phosphorylation, particularly through protein kinase A but probably involving other kinases as well. Channel activity is governed by the 2 nucleotide-binding domains, which regulate channel gating. The carboxyl terminal (consisting of threonine, arginine, and leucine [TRL]) of CFTR is anchored through a PDZ-type binding interaction with the cytoskeleton and is kept in close approximation *(dashed lines)* to a number of important proteins. These associated proteins influence CFTR functions, including conductance, regulation of other channels, signal transduction, and localization at the apical plasma membrane. Each membrane-spanning domain contains 6 membrane-spanning α helixes, portions of which form a chloride-conductance pore. The regulatory domain is a site of protein kinase A phosphorylation. The common F508del mutation occurs on the surface of nucleotide-binding domain 1. *(From Rowe SM, Miller S, Sorscher EJ: Cystic fibrosis,* N Engl J Med *352:1992–2001, 2005.)*

been proposed that abnormal CFTR creates a proinflammatory state or amplifies the inflammatory response to initial infections (viral or bacterial). Some investigators have identified primary differences in CF-affected immune cells and have suggested that these alterations contribute to this proinflammatory state. It appears that inflammatory events occur first in small airways, perhaps because clearance of altered secretions and microorganisms from these regions is more difficult. Chronic bronchiolitis and bronchitis are the initial lung manifestations (see Chapter 391), but after months to years, structural changes in airway walls produce bronchiolectasis and bronchiectasis. The agents of airway injury include neutrophil products, such as oxidative radicals and proteases, and immune reaction products. With advanced lung disease, infection may extend to peribronchial lung parenchyma.

A finding that is not readily explained by CFTR dysfunction is the high prevalence in patients with CF of airway colonization with *Staphylococcus aureus* (see Chapter 181.1), *Pseudomonas aeruginosa* (see Chapter 205.1), and *Burkholderia cepacia* complex (see Chapter 205.2), organisms that rarely infect the lungs of other individuals. It has been postulated that the CF airway epithelial cells or surface liquids may provide a favorable environment for harboring these organisms. CF airway epithelium may be compromised in its innate defenses against these organisms, through either acquired or genetic alterations. Antimicrobial activity is diminished in CF secretions; this diminution may be related to hyperacidic surface liquids or other effects on innate immunity. Another puzzle is the propensity for *P. aeruginosa* to undergo mucoid transformation in the CF airways. The complex polysaccharide produced by these organisms generates a biofilm that provides a hypoxic environment and thereby protects *Pseudomonas* against antimicrobial agents.

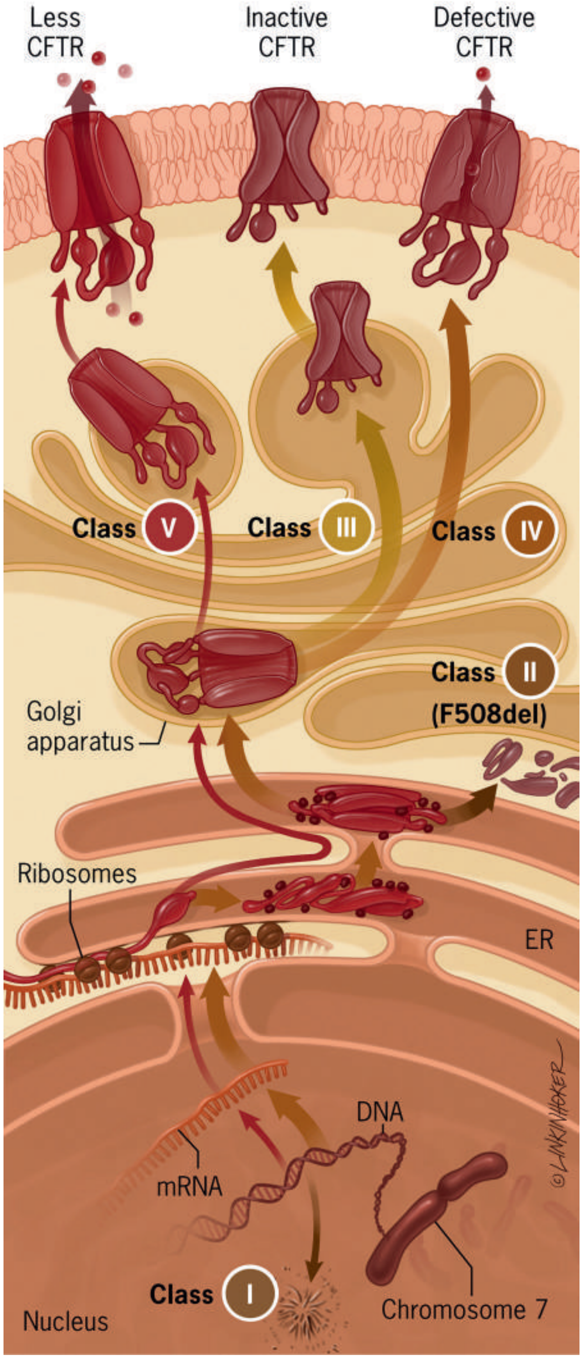

Figure 403-4 **Classes of *CFTR* (cystic fibrosis transmembrane regulator) mutations.** Classes of defects in the *CFTR* gene include the absence of synthesis (class I); defective protein maturation and premature degradation (class II); disordered regulation, such as diminished adenosine triphosphate (ATP) binding and hydrolysis (class III); defective chloride conductance or channel gating (class IV); and a reduced number of CFTR transcripts due to a promoter or splicing abnormality (class V) *(Copyright Michael Linkinhoker, Link Studio.)*

Nutritional deficits, including fatty acid deficiency, have been implicated as predisposing factors for respiratory tract infection. More specifically, concentrations of lipoxins—molecules that suppress neutrophilic inflammation—are suppressed in CF airways. Supporting this idea is the observation that the 10-15% of individuals with CF who retain substantial exocrine pancreatic function have delayed onset of

colonization with *P. aeruginosa* and slower deterioration of lung function. It appears that nutritional factors are only contributory because preservation of pancreatic function does not preclude development of typical lung disease.

PATHOLOGY

The earliest pathologic lesion in the lung is that of **bronchiolitis** (mucous plugging and an inflammatory response in the walls of the small airways); with time, mucus accumulation and inflammation extend to the larger airways (**bronchitis**) (see Chapter 391). Goblet cell hyperplasia and submucosal gland hypertrophy become prominent pathologic findings, which is most likely a response to chronic airway infection. Organisms appear to be confined to the endobronchial space; invasive bacterial infection is not characteristic. With long-standing disease, evidence of airway destruction such as **bronchiolar obliteration, bronchiolectasis,** and **bronchiectasis** (see Chapter 401) becomes prominent. Imaging modalities demonstrate both increased airway wall thickness and luminal cross-sectional area relatively early in lung disease evaluation. Bronchiectatic cysts and emphysematous bullae or subpleural blebs are frequent with advanced lung disease, the upper lobes being most commonly involved. These enlarged air spaces may rupture and cause pneumothorax. Interstitial disease is not a prominent feature, although areas of fibrosis appear eventually. Bronchial arteries are enlarged and tortuous, contributing to a propensity for **hemoptysis** in bronchiectatic airways. Small pulmonary arteries eventually display medial hypertrophy, which would be expected in secondary pulmonary hypertension.

The **paranasal sinuses** are uniformly filled with secretions containing inflammatory products, and the epithelial lining displays hyperplastic and hypertrophied secretory elements (see Chapter 380). Polypoid lesions within the sinuses and erosion of bone have been reported. The nasal mucosa may form large or multiple polyps, usually from a base surrounding the ostia of the maxillary and ethmoidal sinuses.

The **pancreas** is usually small, occasionally cystic, and often difficult to find at postmortem examination. The extent of involvement varies at birth. In infants, the acini and ducts are often distended and filled with eosinophilic material. In 85-90% of patients, the lesion progresses to complete or almost complete disruption of acini and replacement with fibrous tissue and fat. Infrequently, foci of calcification may be seen on radiographs of the abdomen. The islets of Langerhans contain normal-appearing β cells, although they may begin to show architectural disruption by fibrous tissue in the 2nd decade of life.

The **intestinal tract** shows only minimal changes. Esophageal and duodenal glands are often distended with mucous secretions. Concretions may form in the appendiceal lumen or cecum. Crypts of the appendix and rectum may be dilated and filled with secretions.

Focal biliary cirrhosis secondary to blockage of intrahepatic bile ducts is uncommon in early life, although it is responsible for occasional cases of prolonged neonatal jaundice. This lesion becomes much more prevalent and extensive with age and is found in 70% of patients at postmortem examination. This process can proceed to symptomatic multilobular biliary cirrhosis that has a distinctive pattern of large irregular parenchymal nodules and interspersed bands of fibrous tissue. Approximately 30-70% of patients have fatty infiltration of the liver, in some cases despite apparently adequate nutrition. At autopsy, hepatic congestion secondary to cor pulmonale is frequently observed. The gallbladder may be hypoplastic and filled with mucoid material and often contains stones. The epithelial lining often displays extensive mucous metaplasia. Atresia of the cystic duct and stenosis of the distal common bile duct have been observed.

Glands of the **uterine cervix** are distended with mucus, copious amounts of which collect in the cervical canal. In >95% of males, the body and tail of the epididymis, the vas deferens, and the seminal vesicles are obliterated or atretic, resulting in male infertility.

CLINICAL MANIFESTATIONS

Mutational heterogeneity and environmental factors appear responsible for highly variable involvement of the lungs, pancreas, and other organs. A list of presenting manifestations is lengthy, although pulmonary and gastrointestinal presentations predominate (Fig. 403-5). With inclusion of CF newborn screening panels, an increasing proportion of children are diagnosed before symptoms appear.

Respiratory Tract

Cough is the most constant symptom of pulmonary involvement. At first, the cough may be dry and hacking, but eventually it becomes loose and productive. In older patients, the cough is most prominent upon arising in the morning or after activity. Expectorated mucus is usually purulent. Some patients remain asymptomatic for long periods or seem to have prolonged but intermittent acute respiratory infections. Others acquire a chronic cough in the 1st few wk of life, or they

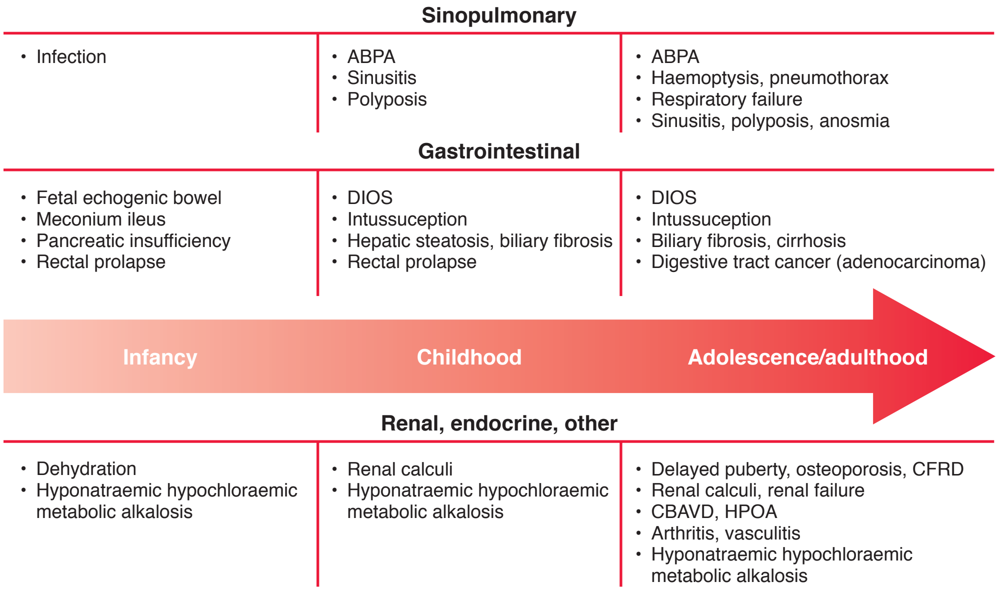

Figure 403-5 Approximate age of onset of clinical manifestations of cystic fibrosis. ABPA, allergic bronchopulmonary aspergillosis; CBAVD, congenital bilateral absence of the vas deferens; CFRD, cystic fibrosis-related diabetes mellitus; DIOS, distal intestinal obstruction syndrome; HPOA, hypertrophic pulmonary osteoarthritis. *(From O'Sullivan BP, Freedman SD: Cystic fibrosis,* Lancet *373:1891–1902, 2009.)*

have pneumonia repeatedly. Extensive bronchiolitis accompanied by wheezing is a frequent symptom during the 1st few yr of life. As lung disease slowly progresses, exercise intolerance, shortness of breath, and failure to gain weight or grow are noted. Exacerbations of lung symptoms, presumably owing to more active airways infection, often require repeated hospitalizations for effective treatment. Cor pulmonale, respiratory failure, and death eventually supervene unless lung transplantation is accomplished. Colonization with *B. cepacia* and other multidrug-resistant organisms may be associated with particularly rapid pulmonary deterioration and death.

The rate of progression of lung disease is the chief determinant of morbidity and mortality. The course of lung disease is largely independent of genotype. Male gender and exocrine pancreatic sufficiency are also associated with a slower rate of pulmonary function decline.

Early **physical findings** include increased anteroposterior diameter of the chest, generalized hyperresonance, scattered or localized coarse crackles, and digital clubbing. Expiratory wheezes may be heard, especially in young children. Cyanosis is a late sign. Common pulmonary complications include atelectasis, hemoptysis, pneumothorax, and cor pulmonale; these usually appear beyond the 1st decade of life.

Even though the paranasal sinuses are virtually always opacified radiographically, acute sinusitis is infrequent. Nasal obstruction and rhinorrhea are common, caused by inflamed, swollen mucous membranes or, in some cases, nasal polyposis. **Nasal polyps** are most troublesome between 5 and 20 yr of age.

Intestinal Tract

In 10-15% of newborn infants with CF, the ileum is completely obstructed by meconium (**meconium ileus**). The frequency is greater (≈30%) among siblings born subsequent to a child with meconium ileus and is particularly striking in monozygotic twins, reflecting a genetic contribution from 1 or more modifying genes. Abdominal distention, emesis, and failure to pass meconium appear in the 1st 24-48 hr of life (see Chapters 102.1 and 330.2). Abdominal radiographs (Fig. 403-6) show dilated loops of bowel with air–fluid levels and, frequently, a collection of granular, "ground-glass" material in the lower central abdomen. Rarely, **meconium peritonitis** results from intrauterine rupture of the bowel wall and can be detected radiographically as the presence of peritoneal or scrotal calcifications. **Meconium plug syndrome** occurs with increased frequency in infants with CF but is less specific than meconium ileus. Ileal obstruction with fecal material *(distal intestinal obstruction syndrome)* occurs in older patients, causing cramping abdominal pain and abdominal distention.

More than 85% of affected children show evidence of protein and fat malabsorption from exocrine pancreatic insufficiency. Symptoms include frequent, bulky, greasy stools and failure to gain weight even when food intake appears to be large. Characteristically, stools contain readily visible droplets of fat. A protuberant abdomen, decreased muscle mass, poor growth, and delayed maturation are typical physical signs. Excessive flatus may be a problem. A number of mutations are associated with preservation of some exocrine pancreatic function, including R117H and 3849 + 10kbC→T. Virtually all individuals homozygous for F508del have pancreatic insufficiency.

Less-common gastrointestinal manifestations include intussusception, fecal impaction of the cecum with an asymptomatic right lower quadrant mass, and epigastric pain owing to duodenal inflammation. Acid or bile reflux with esophagitis symptoms is common in older children and adults. Subacute appendicitis and periappendiceal abscess have been encountered. Historically a relatively common event, rectal prolapse occurs much less frequently as the result of earlier diagnosis and initiation of pancreatic enzyme replacement therapy. Occasionally, hypoproteinemia with anasarca appears in malnourished infants, especially if children are fed soy-based preparations. Neurologic dysfunction (dementia, peripheral neuropathy) and hemolytic anemia may occur because of **vitamin E deficiency.** Deficiency of other fat-soluble vitamins is occasionally symptomatic. **Hypoprothrombinemia** caused by vitamin K deficiency may result in a bleeding diathesis. Clinical manifestations of other fat-soluble vitamin deficiencies, such as decreased bone density and night blindness, have been noted. Rickets is rare.

Biliary Tract

Evidence for liver dysfunction is most often detected in the 1st 15 yr of life and can be found in up to 30% of individuals. Biliary cirrhosis becomes symptomatic in only 5-7% of patients. Manifestations can include icterus, ascites, hematemesis from esophageal varices, and evidence of hypersplenism. A neonatal hepatitis-like picture and massive hepatomegaly owing to steatosis have been reported. Biliary colic secondary to cholelithiasis may occur in the 2nd decade or later. Liver disease occurs independent of genotype but is associated with meconium ileus and pancreatic insufficiency.

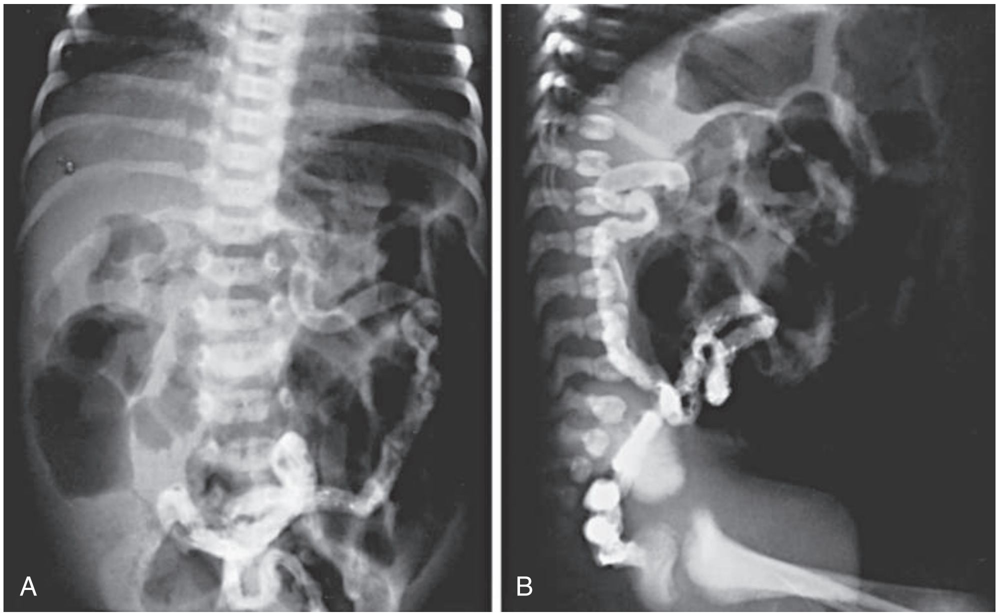

Figure 403-6 **A** and **B,** Contrast enema study in a newborn infant with abdominal distention and failure to pass meconium. Notice the small diameter of the sigmoid and ascending colon and dilated, air-filled loops of small intestine. Several air–fluid levels in the small bowel are visible on the upright lateral view.

Cystic Fibrosis–Related Diabetes and Pancreatitis

In addition to exocrine pancreatic insufficiency, evidence for hyperglycemia and glucosuria, including polyuria and weight loss, may appear, especially in the 2nd decade of life. Ketoacidosis usually does not occur, but eye, kidney, and other vascular complications have been noted in patients living ≥10 yr after the onset of hyperglycemia. Recurrent, acute pancreatitis occurs occasionally in individuals who have residual exocrine pancreatic function and may be the sole manifestation of 2 *CFTR* mutations.

Genitourinary Tract

Sexual development is often delayed but only by an average of 2 yr. More than 95% of males are azoospermic because of failure of development of wolffian duct structures, but sexual function is generally unimpaired. The incidence of inguinal hernia, hydrocele, and undescended testis is higher than expected. Adolescent females may experience secondary amenorrhea, especially with exacerbations of pulmonary disease. The female fertility rate is diminished. Pregnancy is generally tolerated well by women with good pulmonary function but may accelerate pulmonary progression in those with moderate or advanced lung problems. Urinary incontinence associated with cough occurs in 18-47% of female children and adolescents.

Sweat Glands

Excessive loss of salt in the sweat predisposes young children to salt depletion episodes, especially during episodes of gastroenteritis and during warm weather. These children present with **hypochloremic alkalosis.** Hyponatremia is a risk particularly in warm climates. Frequently, parents notice salt "frosting" of the skin or a salty taste when they kiss the child. A few genotypes are associated with normal sweat chloride values.

DIAGNOSIS AND ASSESSMENT

The diagnosis of CF has been based on a positive quantitative sweat test (Cl^- ≥60 mEq/L) in conjunction with 1 or more of the following features: typical chronic obstructive pulmonary disease, documented exocrine pancreatic insufficiency, and a positive family history. With newborn screening, diagnosis is often made prior to obvious clinical manifestations such as failure to thrive and chronic cough. Diagnostic criteria have been recommended to include additional testing procedures (Table 403-3).

Sweat Testing

The sweat test, which involves using pilocarpine iontophoresis to collect sweat and performing chemical analysis of its chloride content, is the standard approach to diagnosis of CF. The procedure requires care and accuracy. An electric current is used to carry pilocarpine into the skin of the forearm and locally stimulate the sweat glands. If an adequate amount of sweat is collected, the specimens are analyzed for chloride concentration. Testing may be difficult in the 1st 2 wk of life because of low sweat rates but is recommended any time after the 1st 48 hr of life. Positive results should be confirmed; for a negative result, the test should be repeated if suspicion of the diagnosis remains.

More than 60 mEq/L of chloride in sweat is diagnostic of CF when 1 or more other criteria are present. Threshold levels of 30-40 mEq/L for infants have been suggested. Borderline (or intermediate) values of 40-60 mEq/L have been reported in patients of all ages who have CF with atypical involvement and require further testing. Chloride concentrations in sweat are somewhat lower in individuals who retain exocrine pancreatic function but usually remain within the diagnostic range. Table 403-4 lists the conditions associated with false-negative and false-positive sweat test results.

Table 403-3	Diagnostic Criteria for Cystic Fibrosis (CF)

Presence of typical clinical features (respiratory, gastrointestinal, or genitourinary)
or
A history of CF in a sibling
or
A positive newborn screening test
plus
Laboratory evidence for CFTR (CF transmembrane regulator) dysfunction:
- Two elevated sweat chloride concentrations obtained on separate days
- *or*
- Identification of two CF mutations
- *or*
- An abnormal nasal potential difference measurement

DNA Testing

Several commercial laboratories test for 30-96 of the most common *CFTR* mutations. This testing identifies ≥90% of individuals who carry 2 CF mutations. Some children with typical CF manifestations are found to have 1 or no detectable mutations by this methodology. Some laboratories perform comprehensive mutation analysis screening for all of the >1,900 identified mutations.

Other Diagnostic Tests

The finding of increased potential differences across nasal epithelium (nasal potential difference) that is the increased voltage response to topical amiloride application, followed by the absence of a voltage response to a β-adrenergic agonist, has been used to confirm the diagnosis of CF in patients with equivocal or frankly normal sweat chloride values.

Pancreatic Function

Exocrine pancreatic dysfunction is clinically apparent in many patients. Documentation is desirable if there are questions about the functional status of the pancreas. The diagnosis of pancreatic malabsorption can be made by the quantification of elastase-1 activity in a fresh stool sample by an enzyme-linked immunosorbent assay specific for human elastase. To determine the degree of fat malabsorption, a 72 hr stool

Table 403-4	Conditions Associated with False-Positive and False-Negative Sweat Test Results

WITH FALSE-POSITIVE RESULTS
Eczema (atopic dermatitis)
Ectodermal dysplasia
Malnutrition/failure to thrive/deprivation
Anorexia nervosa
Congenital adrenal hyperplasia
Adrenal insufficiency
Glucose-6-phosphatase deficiency
Mauriac syndrome
Fucosidosis
Familial hypoparathyroidism
Hypothyroidism
Nephrogenic diabetes insipidus
Pseudohypoaldosteronism
Klinefelter syndrome
Familial cholestasis syndrome
Autonomic dysfunction
Prostaglandin E infusions
Munchausen syndrome by proxy

WITH FALSE-NEGATIVE RESULTS
Dilution
Malnutrition
Edema
Insufficient sweat quantity
Hyponatremia
Cystic fibrosis transmembrane conductance regulator mutations with preserved sweat duct function

collection is performed for total fat quantitation with a simultaneous diet history to determine a coefficient of fat absorption. Normal fat absorption is greater than 93% of fat ingestion. Endocrine pancreatic dysfunction may be more prevalent than previously recognized. Cystic fibrosis–related diabetes affects approximately 19% of adolescents and 40-50% of adults. Many authorities advocate yearly monitoring with a modified 2 hr oral glucose tolerance test after 10 yr of age. This approach is more sensitive than spot checks of blood and urine glucose levels and glycosylated hemoglobin levels.

Radiology

Pulmonary radiologic findings suggest the diagnosis but are not specific. Hyperinflation of lungs occurs early and may be overlooked in the absence of infiltrates or streaky densities. Bronchial thickening and plugging and ring shadows suggesting bronchiectasis usually appear first in the upper lobes. Nodular densities, patchy atelectasis, and confluent infiltrate follow. Hilar lymph nodes may be prominent. With advanced disease, impressive hyperinflation with markedly depressed diaphragms, anterior bowing of the sternum, and a narrow cardiac shadow are noted. Cyst formation, extensive bronchiectasis, dilated pulmonary artery segments, and segmental or lobar atelectasis is often apparent with advanced disease. Figure 403-7 shows typical progression of lung disease. Most CF centers obtain chest radiographs (posteroanterior [PA] and lateral) at least annually. Standardized scoring of roentgenographic changes has been used to follow progression of lung disease. CT of the chest can detect and localize thickening of bronchial airway walls, mucous plugging, focal hyperinflation, and early bronchiectasis (Fig. 403-8); it is generally not used for routine evaluation of chest disease. Many children with normal lung function have bronchiectasis on CT, indicating that this imaging modality is sensitive to early lung changes.

Radiographs of paranasal sinuses reveal panopacification and, often, failure of frontal sinus development. CT provides better resolution of sinus changes if this information is required clinically. Fetal ultrasonography may suggest ileal obstruction with meconium early in the 2nd trimester, but this finding is not predictive of meconium ileus at birth.

Pulmonary Function

Standard pulmonary function studies are not obtained until patients are 4-6 yr of age, by which time many patients show the typical pattern of obstructive pulmonary involvement (see Chapter 384). Decrease in the midmaximal flow rate is an early functional change, reflecting small airway obstruction. This lesion also affects the distribution of

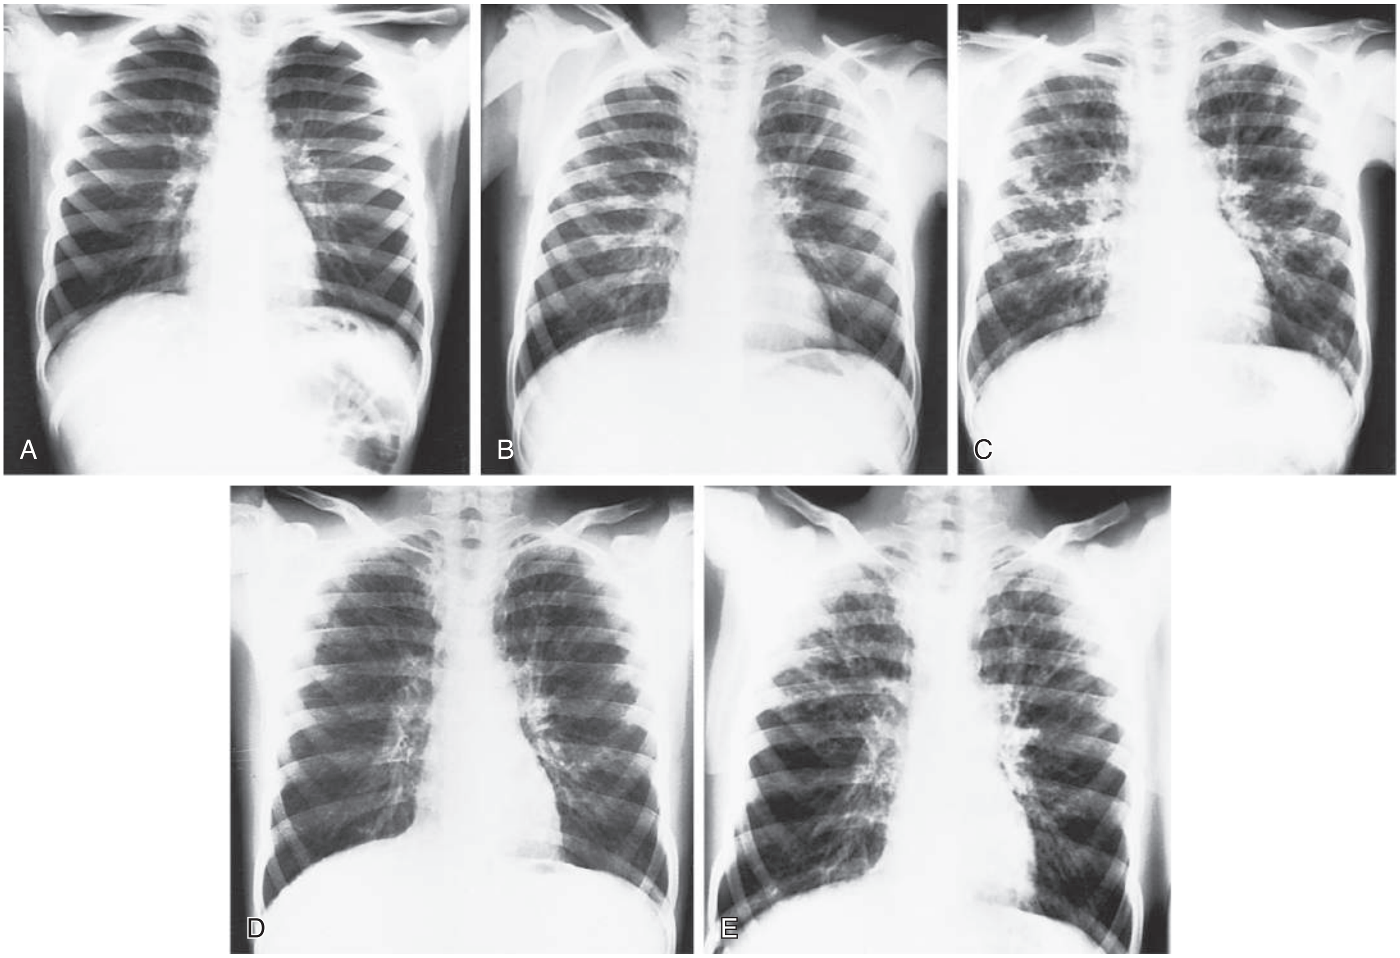

Figure 403-7 Serial radiographs in a boy show the changing appearance of cystic fibrosis over 6 yr. **A,** At 9 yr, frontal radiograph shows minimal peribronchial thickening and hyperaerated lungs indistinguishable from asthma. **B,** Nineteen months later, the radiographic picture has worsened considerably. Extensive peribronchial thickening is now noted. Mucoid impaction of the bronchus is seen in the left upper lobe and hilar shadows have become abnormally prominent. **C,** Ten months later, further deterioration is obvious. Widespread typical changes of CF are noted throughout both lungs. **D,** Follow-up studies show considerable improvement, which suggested that some of the changes evident on **C** were from superimposed infection. **E,** One year later, note the progressive changes of CF—most severe in the upper lobes bilaterally. *(From Long FR, Druhan SM, Kuhn JP. Diseases of the bronchi and pulmonary aeration. In Slovis TL, editor,* Caffey's pediatric diagnostic imaging, *ed 11, Philadelphia, 2008, Mosby,* Fig. 73-54.*)*

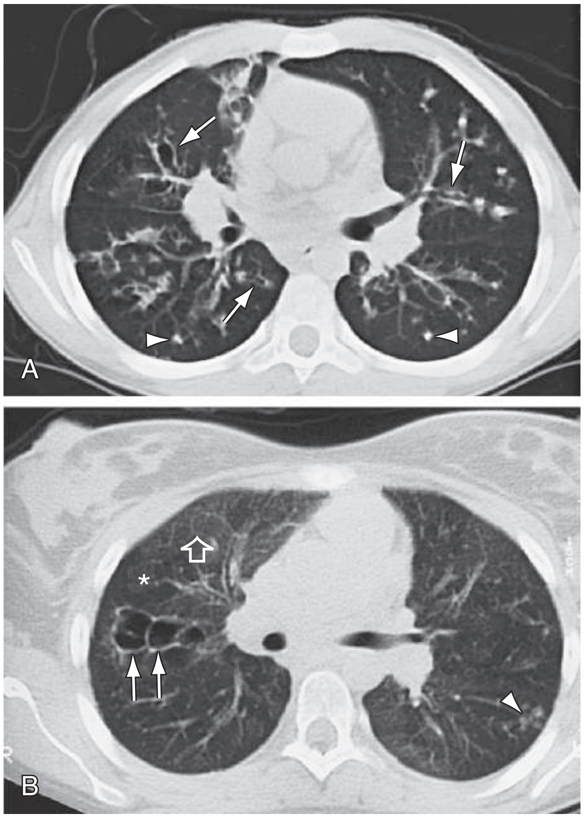

Figure 403-8 CT scans of the chest in cystic fibrosis. **A,** A 12 yr old boy with moderate lung disease. Airway and parenchymal changes are present throughout both lungs. Multiple areas of bronchiectasis *(arrows)* and mucous plugging *(arrowheads)* can be seen. **B,** A 19 yr old girl has mostly normal lung with 1 area of saccular bronchiectasis in the right upper lobe *(arrows)* and a focal area of peripheral mucous plugging in the right lower lobe *(arrowhead).* Lung density is heterogeneous with areas of normal lung *(open arrow)* and areas of low attenuation reflecting segmental and subsegmental air trapping *(asterisk).*

ventilation and increases the alveolar-arterial oxygen difference. The findings of obstructive airway disease and modest responses to a bronchodilator are consistent with the diagnosis of CF at all ages. Residual volume and functional residual capacity are increased early in the course of lung disease. Restrictive changes, characterized by declining total lung capacity and vital capacity, correlate with extensive lung injury and fibrosis and are a late finding. Testing at each clinic visit is recommended to evaluate the course of the pulmonary involvement and allow for early intervention when substantial decrements are documented. Increasing numbers of CF centers are equipped to measure airflow patterns of sedated infants (infant pulmonary function tests). Some patients reach adolescent or adult life with normal pulmonary function and without evidence of overinflation.

Microbiologic Studies

The finding of *S. aureus* or *P. aeruginosa* on culture of the lower airways (sputum) strongly suggests a diagnosis of CF. In particular, mucoid forms of *P. aeruginosa* are often recovered from CF lungs. *B. cepacia complex* recovery also suggests CF. A wide range of other organisms are frequently recovered, particularly in advanced lung disease; they include a variety of Gram-negative rods including *Stenotrophomonas maltophilia*, and *Achromobacter xylosoxidans*, fungi, and nontuberculous mycobacterial species. Failure of respiratory symptom flares to respond to usual antibiotics triggers testing for *Mycoplasma* and viruses. Fiberoptic bronchoscopy is used to gather lower respiratory tract secretions of infants and young children who do not expectorate.

Heterozygote Detection and Prenatal Diagnosis

Mutation analysis should be fully informative for testing of potential carriers or a fetus, provided that mutations within the family have been previously identified. Testing a spouse of a carrier with a standard panel of probes is ≈90% sensitive, and full CFTR sequence analysis is commercially available if further testing is warranted. Prenatal testing should be offered to all couples planning to have children in addition to individuals with a family history of CF and partners of CF women. The American College of Medical Genetics and the American College of Obstetricians and Gynecologists recommend that CF carrier screening be offered to individuals of Ashkenazi Jewish or white descent and be made available to individuals of other ethnic and racial groups; in one large series, 14% of carrier screening referrals were from Hispanic and African-American individuals, and 12% from individuals with ethnicities other than white or Ashkenazi Jewish. Screening of the siblings of an affected child is also suggested.

Newborn Screening

Newborn screening for CF is mandated in all 50 states. A variety of newborn screening algorithms are in place to identify infants with CF. Most algorithms utilize a combination of immunoreactive trypsinogen results and limited DNA testing on blood spots; all positive screens are followed by a confirmatory sweat analysis. This screening test is ≈95% sensitive. Newborn diagnoses can prevent early nutritional deficiencies and improve long-term growth and may improve cognitive function. Importantly, good nutritional status (50% weight for height or 50% body mass index) is associated with better lung function at 6 yr of age. There is a subset of infants with a positive newborn screen for CF, elevated immunoreactive trypsinogen and 1 or 2 copies of a CFTR mutation, but who have an initial negative sweat test and are asymptomatic. These infants have **CFTR** metabolic syndrome and should be followed in a CF center annually to ensure that they do not develop CF symptoms. Indeed, in some the sweat test becomes abnormal over time; nonetheless if they develop CF the manifestations are mild.

TREATMENT

The treatment plan should be comprehensive and linked to close monitoring and early, aggressive intervention.

General Approach to Care

Initial efforts after diagnosis should be intensive and should include baseline assessment, initiation of treatment, clearing of pulmonary involvement, and education of the patient and parents. Follow-up evaluations are scheduled every 1-3 mo, depending on the age at diagnosis, because many aspects of the condition require careful monitoring. An interval history and physical examination should be obtained at each visit. A sputum sample or, if that is not available, a lower pharyngeal swab taken during or after a forced cough is obtained for culture and antibiotic susceptibility studies. Because irreversible loss of pulmonary function from low-grade infection can occur gradually and without acute symptoms, emphasis is placed on a thorough pulmonary history. Table 403-5 lists symptoms and signs that suggest the need for more intensive antibiotic and physical therapy. Protection against exposure to methicillin-resistant *S. aureus, P. aeruginosa, B. cepacia,* and other resistant Gram-negative organisms is essential, including isolation procedures and careful attention to sterilization of inhalation therapy equipment. A nurse, physical therapist, respiratory therapist, social worker, and dietitian, as members of the multidisciplinary care team, should evaluate children regularly and contribute to the development of a comprehensive daily care plan. Considerable education and programs to empower families and older children to take responsibility for care are likely to result in the best adherence to daily care programs. Standardization of practice, on the part of both caregivers and families, as well as close monitoring and early intervention for new or increasing symptoms appears to result in the best long-term outcomes.

Because secretions of CF patients are not adequately hydrated, attention in early childhood to oral hydration, especially during warm weather or with acute gastroenteritis, may minimize complications

Table 403-5 Symptoms and Signs Associated with Exacerbation of Pulmonary Infection in Patients with Cystic Fibrosis

SYMPTOMS
Increased frequency and duration of cough
Increased sputum production
Change in appearance of sputum
Increased shortness of breath
Decreased exercise tolerance
Decreased appetite
Feeling of increased congestion in the chest
SIGNS
Increased respiratory rate
Use of accessory muscles for breathing
Intercostal retractions
Change in results of auscultatory examination of chest
Decline in measures of pulmonary function consistent with the presence of obstructive airway disease
Fever and leukocytosis
Weight loss
New infiltrate on chest radiograph

From Ramsey B: Management of pulmonary disease in patients with cystic fibrosis, N Engl J Med *335:179, 1996.*

Table 403-6 Complications of Therapy for Cystic Fibrosis*

COMPLICATION	AGENT
Gastrointestinal bleeding	Ibuprofen
Hyperglycemia	Corticosteroids (systemic)
Growth retardation	Corticosteroids (systemic, inhaled)
Renal dysfunction:	
Tubular	Aminoglycosides
Interstitial nephritis	Semisynthetic penicillins, nonsteroidal antiinflammatory drugs
Hearing loss, vestibular dysfunction	Aminoglycosides
Peripheral neuropathy or optic atrophy	Chloramphenicol (prolonged course)
Hypomagnesemia	Aminoglycosides
Hyperuricemia, colonic stricture	Pancreatic extracts (very large doses)
Goiter	Iodine-containing expectorants
Gynecomastia	Spironolactone
Enamel hypoplasia or staining	Tetracyclines (used in 1st 8 yr of life)

*Common hypersensitivity reactions to drugs are not included.

associated with impaired mucus clearance. Intravenous therapy for dehydration should be initiated early.

The goal of therapy is to maintain a stable condition for prolonged periods. This can be accomplished for most patients by interval evaluation and adjustments of the home treatment program. Some children have episodic acute or low-grade chronic lung infection that progresses. For these patients, intensive inhalation and airway clearance and intravenous antibiotics are indicated. Improvement is most reliably accomplished in a hospital setting; selected patients have demonstrated successful outcomes while completing these treatments at home. Intravenous antibiotics may be required infrequently or as often as every 2-3 mo. The goal of treatment is to return patients to their previous pulmonary and functional status.

The basic daily care program varies according to the age of the child, the degree of pulmonary involvement, other system involvement, and the time available for therapy. The major components of this care are pulmonary and nutritional therapies. Because therapy is medication-intensive, iatrogenic problems frequently arise. Monitoring for these complications is also an important part of management (Table 403-6).

Pulmonary Therapy

The object of pulmonary therapy is to clear secretions from airways and to control infection. When a child is not doing well, every potentially useful aspect of therapy should be reconsidered.

Inhalation Therapy

Aerosol therapy is used to deliver medications and hydrate the lower respiratory tract. Metered-dose inhalers can deliver some agents, such as bronchodilators and corticosteroids, with a spacer for younger children. Alternately, these medications can be delivered with a compressor that drives a handheld nebulizer. In some patients β-agonists may decrease $Pa{O_2}$ acutely by increasing ventilation-perfusion mismatch, a concern if the $Pa{O_2}$ is marginal.

Human recombinant DNase (2.5 mg), given as a single daily aerosol dose, improves pulmonary function, decreases the number of pulmonary exacerbations, and promotes a sense of well-being in patients who have moderate disease and purulent secretions. Benefit for those with normal forced expiratory volume in 1 sec (FEV_1) values or advanced lung disease has also been documented. Improvement is sustained for 12 mo or longer with continuous therapy. Another mucolytic agent, *N*-acetylcysteine, nebulized as a 5-10% solution following β_2-agonist nebulization, is useful for airway clearance and may potentially augment airway levels of the antioxidant, glutathione.

Nebulized hypertonic saline, acting as a hyperosmolar agent, is believed to draw water into the airway and rehydrate mucus and the periciliary fluid layer, resulting in improved mucociliary clearance. A number of studies have reported that 7% hypertonic saline nebulized 2-4 times daily results in increased mucus clearance and improved pulmonary function.

Aerosolized antibiotics are often used when the airways are colonized with *Pseudomonas* as part of daily therapy. Aerosolized tobramycin, TOBI, or aerosolized aztreonam, Cayston, used as a suppressive therapy (on 1 mo, off 1 mo) may reduce symptoms, improve pulmonary function, and alleviate the need for hospitalization (see "Aerosolized Antibiotic Therapy" below).

Airway Clearance Therapy

Airway clearance treatment usually consists of chest percussion combined with postural drainage and derives its rationale from the idea that cough clears mucus from large airways but chest vibrations are required to move secretions from small airways, where expiratory flow rates are low. **Chest physical therapy (PT)** can be particularly useful for patients with CF because they accumulate secretions in small airways first, even before the onset of symptoms. Although immediate improvement of pulmonary function generally cannot be demonstrated after PT, cessation of chest PT in children with mild to moderate airflow limitation results in deterioration of lung function within 3 wk, and prompt improvement of function occurs when therapy is resumed. Chest PT is recommended 1-4 times a day, depending on the severity of lung dysfunction. Cough, huffing, or forced expirations are encouraged after each lung segment is "drained." Vest-type mechanical percussors are also useful. Voluntary coughing, repeated forced expiratory maneuvers with and without positive expiratory pressure, patterned breathing, and use of an array of handheld oscillatory devices are additional aids to clearance of mucus. Routine aerobic exercise appears to slow the rate of decline of pulmonary function, and benefit has also been documented with weight training. No one airway clearance technique is superior to any other, so all modes should be considered in the development of an airway clearance prescription.

Adherence to daily therapy is essential; therefore airway clearance technique plans are individualized for each patient.

Antibiotic Therapy

Antibiotics are the mainstay of therapy designed to control progression of lung infection. The goal is to reduce the intensity of endobronchial infection and to delay progressive lung damage. The usual guidelines for acute chest infections, such as fever, tachypnea, or chest pain, are often absent. Consequently, all aspects of the patient's history and examination, including anorexia, weight loss, and diminished activity, must be used to guide the frequency and duration of therapy. Antibiotic treatment varies from intermittent short courses of 1 antibiotic to nearly continuous treatment with 1 or more antibiotics. Dosages for some antibiotics are often 2-3 times the amount recommended for minor infections because patients with CF have proportionately more lean body mass and higher clearance rates for many antibiotics than other individuals. In addition, it is difficult to achieve effective drug levels of many antimicrobials in respiratory tract secretions.

Oral Antibiotic Therapy

Indications for oral antibiotic therapy in a patient with CF include the presence of respiratory tract symptoms and identification of pathogenic organisms in respiratory tract cultures. Whenever possible, the choice of antibiotics should be guided by in vitro sensitivity testing. Common organisms, including *S. aureus,* nontypeable *Haemophilus influenzae, P. aeruginosa; B. cepacia* and other Gram-negative rods, are encountered with increasing frequency. The first 2 can be eradicated from the respiratory tract in CF with use of oral antibiotics, but *Pseudomonas* is more difficult to treat. The usual course of therapy is ≥2 wk, and maximal doses are recommended. Table 403-7 lists useful oral antibiotics. The quinolones are the only broadly effective oral antibiotics for *Pseudomonas* infection, but resistance against these agents emerges rapidly. Infection with mycoplasma or chlamydial organisms has been documented, providing a rationale for the use of macrolides on an empirical basis for flare of symptoms. Macrolides may reduce the virulence properties of *P. aeruginosa,* such as biofilm production, and contribute antiinflammatory effects. Long-term therapy with azithromycin 3 times a week improves lung function in patients with chronic *P. aeruginosa* infection.

Aerosolized Antibiotic Therapy

P. aeruginosa and other Gram-negative organisms are frequently resistant to all oral antibiotics. Aerosol delivery of antibiotics has been used as an option for home delivery of additional agents, such as tobramycin, colistin, and gentamicin. Although these therapies are used, the evidence to support aerosolized antibiotics for an acute pulmonary exacerbation is limited. However, there is good evidence to support the use of inhaled tobramycin as a long-term suppressive therapy in a patient colonized with *P. aeruginosa*. When tobramycin is given at a dose of 300 mg twice daily on alternate months for 6 mo, *Pseudomonas* density in sputum decreases, fewer hospitalizations are required, and pulmonary function can improve by ≥10%. Toxicity is negligible. On the basis of available evidence, this therapy is recommended in patients with chronic colonization with *P. aeruginosa,* to lessen symptoms and/or to improve long-term function in patients with moderate to severe disease. Recently, nebulized aztreonam was also approved for 3 times daily therapy on alternate months for patients with chronic *P. aeruginosa*. Another indication for aerosolized antibiotic therapy is to eradicate *P. aeruginosa* in the airways after initial colonization. Early infection may be cleared for months to several years by several protocols, including oral ciprofloxacin and/or aerosolized colistin or tobramycin. However, once chronically established, *P. aeruginosa* infection is rarely eradicated.

Intravenous Antibiotic Therapy

For the patient who has progressive or unrelenting symptoms and signs despite intensive home measures, intravenous antibiotic therapy is indicated. This therapy is usually initiated in the hospital but may be

Table 403-7 Antimicrobial Agents for Cystic Fibrosis Lung Infection

ROUTE	ORGANISMS	AGENTS	DOSAGE (mg/kg/24 hr)	NO. DOSES/24 hr
Oral	*Staphylococcus aureus*	Dicloxacillin	25-50	4
		Linezolid	20	2
		Cephalexin	50	4
		Clindamycin	10-30	3-4
		Amoxicillin-clavulanate	25-45	2-3
	Haemophilus influenzae	Amoxicillin	50-100	2-3
	Pseudomonas aeruginosa	Ciprofloxacin	20-30	2-3
	Burkholderia cepacia	Trimethoprim-sulfamethoxazole	8-10*	2-4
	Empirical	Azithromycin	10, day 1; 5, days 2-5	1
		Erythromycin	30-50	3-4
Intravenous	*S. aureus*	Nafcillin	100-200	4-6
		Vancomycin	40	3-4
	P. aeruginosa	Tobramycin	8-12	1-3
		Amikacin	15-30	2-3
		Ticarcillin	400	4
		Piperacillin	300-400	4
		Ticarcillin-clavulanate	400†	4
		Piperacillin-tazobactam	240-400‡	3
		Meropenem	60-120	3
		Imipenem-cilastatin	45-100	3-4
		Ceftazidime	150	3
		Aztreonam	150-200	4
	B. cepacia	Chloramphenicol	50-100	4
		Meropenem	60-120	3
Aerosol		Tobramycin (inhaled)	300§	2
		Aztreonam (inhaled)	75	3

†Quantity of ticarcillin.
‡Quantity of piperacillin.
§In mg per dose.

completed on an ambulatory basis. Although many patients show improvement within 7 days, it is usually advisable to extend the period of treatment to at least 14 days. Permanent intravenous access can be provided for long-term or frequent courses of therapy in the hospital or at home. Thrombophilia screening should be considered before the use of totally implantable intravenous devices or for recurring problems with venous catheters.

Table 403-7 lists commonly used intravenous antibiotics. In general, treatment of *Pseudomonas* infection requires 2-drug therapy. A third agent may be required for optimal coverage of *S. aureus* or other organisms. The aminoglycosides have a relatively short half-life in many patients with CF. The initial parenteral dose, noted in Table 403-7, is generally given every 8 hr. After blood levels have been determined, the total daily dose should be adjusted. Peak levels of 10-15 mg/L are desirable, and trough levels should be kept at <2 mg/L to minimize the risk of ototoxicity and nephrotoxicity. The regimen of once-daily tobramycin dosing has been demonstrated to have equivalent efficacy and the advantage of decreased toxicity over dosing every 8 hr. For once-daily dosing of tobramycin, peak levels should be between 20 and 30 mg/L and trough levels should be 1 mg/L or less. In toddlers, older children, and adults, once-daily intravenous tobramycin therapy is becoming the standard of care. Changes in therapy should be guided by lack of improvement and by culture results. If patients do not show improvement, complications such as heart failure and reactive airways or infection with viruses, *Aspergillus fumigatus* (see Chapter 237), nontuberculous mycobacteria (see Chapters 217 and 399), or other unusual organisms should be considered. *B. cepacia* complex is the most frequent of a growing list of Gram-negative rods that may be particularly refractory to antimicrobial therapy. Infection control in both the outpatient and inpatient medical setting is critically important to prevent nosocomial spread of resistant bacterial organisms between patients.

Bronchodilator Therapy

Reversible airway obstruction occurs in many children with CF, sometimes in conjunction with frank asthma or acute bronchopulmonary aspergillosis. Reversible obstruction is defined as improvement of ≥12% in flow rates after inhalation of a bronchodilator. In many patients with CF, flow rates may improve by only 5-10%, however. Nevertheless, subjective benefit is claimed by many following use of a β-adrenergic agonist aerosol. Cromolyn sodium and ipratropium hydrochlorides are alternative agents, but there is no evidence to support their use.

Antiinflammatory Agents

Corticosteroids are useful for the treatment of allergic bronchopulmonary aspergillosis and severe reactive airway disease occasionally encountered in children with CF. Prolonged treatment of standard CF lung disease using an alternate-day regimen initially appeared to improve pulmonary function and diminish hospitalization rates. However, a 4-yr double-blind, multicenter study of this regimen for patients with mild to moderate lung disease found only modest efficacy and prohibitive side effects, including growth retardation, cataracts, and abnormalities of glucose tolerance at a dose of 2 mg/kg and growth retardation at 1 mg/kg. Inhaled corticosteroids have theoretical appeal, but there are few data documenting their efficacy and safety; it appears that discontinuing inhaled corticosteroids in patients with CF had no effect on lung function, antibiotic use, or bronchodilator use. Ibuprofen, given long term (dose adjusted to achieve a peak serum concentration of 50-100 μg/mL) for 4 yr, is associated with a slowing of disease progression, particularly in younger patients with mild lung disease. Side effects of nonsteroidal antiinflammatory drugs have been encountered (see Table 403-6); therefore, this therapy has not gained broad acceptance even though ibuprofen is the only antiinflammatory agent with documented efficacy in the patient population.

Endoscopy and Lavage

Treatment of obstructed airways sometimes includes tracheobronchial suctioning or lavage, especially if atelectasis or mucoid impaction is present. Bronchopulmonary lavage can be performed by the instillation of saline or a mucolytic agent through a fiberoptic bronchoscope. Antibiotics (usually gentamicin or tobramycin) can also be instilled directly at lavage in order to transiently achieve a much higher endobronchial concentration than can be obtained by using intravenous therapy. There is no evidence for sustained benefit from repeated endoscopic or lavage procedures.

Other Therapies

Expectorants such as iodides and guaifenesin do not effectively assist with the removal of secretions from the respiratory tract. Inspiratory muscle training can enhance maximum oxygen consumption during exercise as well as FEV_1.

Emerging Therapies

A major breakthrough in CF therapy is ivacaftor, a small molecule potentiator of the CFTR mutation, G551D (present in ~5% of patients). Ivacaftor activates the CFTR-G551D mutant protein, a class III CFTR mutation that results in protein localized to the plasma membrane but loss of chloride channel function. Ivacaftor therapy resulted in improvement in FEV_1 by an average of 10.6%, decreased the frequency of pulmonary exacerbations by 55%, decreased sweat chloride by an average of 48 mEq/L, and increased weight gain by an average of 2.7 kg. Ivacaftor is approved for CFTR-G551D patients ≥6 yr old, as a 150 mg, twice per day, oral therapy. Additional small molecule correctors are being tested for use in combination with Ivacaftor to correct the processing of the most common CFTR mutation, F508del. The goal of this strategy is to correct the localization of the protein to the apical membrane of the cell and then to potentiate its function.

TREATMENT OF PULMONARY COMPLICATIONS

Atelectasis

Lobar atelectasis occurs relatively infrequently; it may be asymptomatic and noted only at the time of a routine chest radiograph. Aggressive intravenous therapy with antibiotics and increased chest PT directed at the affected lobe may be effective. If there is no improvement in 5-7 days, bronchoscopic examination of the airways may be indicated. If the atelectasis does not resolve, continued intensive home therapy is indicated, because atelectasis may resolve during a period of weeks or months. Lobectomy should be considered only if expansion is not achieved and the patient has progressive difficulty from fever, anorexia, and unrelenting cough (see Chapter 408).

Hemoptysis

Endobronchial bleeding usually reflects airway wall erosion secondary to infection. With increasing numbers of older patients, hemoptysis has become a relatively frequent complication. Blood streaking of sputum is particularly common. Small-volume hemoptysis (<20 mL) should not trigger panic and is usually viewed as a need for intensified antimicrobial therapy and chest PT. When the hemoptysis is persistent or increases in severity, hospital admission is indicated. **Massive hemoptysis,** defined as total blood loss of ≥250 mL in a 24-hr period, is rare in the 1st decade and occurs in <1% of adolescents, but it requires close monitoring and the capability to replace blood losses rapidly. Chest PT is often discontinued until 12-24 hr after the last brisk bleeding episode and is then gradually re-instituted. Patients should receive vitamin K for an abnormal prothrombin time. During brisk hemoptysis, the child and parents require a great deal of reassurance that the bleeding will stop. Blood transfusion is not indicated unless there is hypotension or the hematocrit is significantly reduced. Ticarcillin, salicylates, and nonsteroidal antiinflammatory drugs interfere with platelet function and may aggravate hemoptysis. Bronchoscopy rarely reveals the site of bleeding. Lobectomy is to be avoided, if possible, because functioning lung should be preserved. Bronchial artery embolization can be useful to control persistent, significant hemoptysis.

Pneumothorax

Pneumothorax (see Chapter 411) is encountered in <1% of children and teenagers with CF, although it is more frequently encountered in

older patients and may be life-threatening. The episode may be asymptomatic but is often attended by chest and shoulder pain, shortness of breath, or hemoptysis. A small air collection that does not grow can be observed closely. Chest tube placement with or without pleurodesis is often the initial therapy. Intravenous antibiotics are also begun on admission. An open thoracotomy or video-assisted thoracoscopy with plication of blebs, apical pleural stripping, and basal pleural abrasion should be considered if the air leak persists. Surgical intervention is usually well tolerated even in cases of advanced lung disease. The thoracotomy tube is removed as soon as possible, usually on the 2nd or 3rd postoperative day. The patient can then be mobilized, and full postural drainage therapy resumed. Previous pneumothorax with or without pleurodesis is not a contraindication to subsequent lung transplantation.

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis occurs in 5-10% of patients with CF and may manifest as wheezing, increased cough, shortness of breath, and marked hyperinflation (see Chapters 237 and 399). In some patients, a chest radiograph shows new, focal infiltrates. The presence of rust-colored sputum, the recovery of *Aspergillus* organisms from the sputum, a positive skin test for *A. fumigatus*, the demonstration of specific immunoglobulin (Ig) E and IgG antibodies against *A. fumigatus,* or the presence of eosinophils in a fresh sputum sample supports the diagnosis. The serum IgE level is usually high. Treatment is directed at controlling the inflammatory reaction with oral corticosteroids. For refractory cases, oral antifungals may be required.

Nontuberculous Mycobacteria Infection

See Chapter 217.

Injured airways with poor clearance may be colonized by *Mycobacterium avium-complex* but also *Mycobacterium abscessus*, *Mycobacterium chelonae*, and *Mycobacterium kansasii.* Distinguishing endobronchial colonization (frequent) from invasive infection (infrequent) is challenging. Persistent fevers and new infiltrates or cystic lesions coupled with the finding of acid-fast organisms on sputum smear suggest infection. Treatment is prolonged and requires multiple antimicrobial agents. Symptoms may improve, but the nontuberculous mycobacteria are not usually cleared from the lungs.

Bone and Joint Complications

Hypertrophic osteoarthropathy causes elevation of the periosteum over the distal portions of long bones and bone pain, overlying edema, and joint effusions. Acetaminophen or ibuprofen may provide relief. Control of lung infection usually reduces symptoms. Intermittent arthropathy unrelated to other rheumatologic disorders occurs occasionally, has no recognized pathogenesis, and usually responds to nonsteroidal antiinflammatory agents. Back pain or rib fractures from vigorous coughing may require pain management to permit adequate airway clearance. These and other fractures may stem from diminished bone mineralization, the result of reduced vitamin D absorption, corticosteroid therapy, diminished weight-bearing exercises, and, perhaps, other factors. There may be a bone phenotype in CF that is unrelated to therapies or nutritional status and may be due to CFTR dysfunction.

Sleep-Disordered Breathing

Particularly with advanced pulmonary disease and during chest exacerbations, individuals with CF may experience more sleep arousals, less time in rapid eye movement sleep, nocturnal hypoxemia, hypercapnia, and associated neurobehavioral impairment. Nocturnal hypoxemia may hasten the onset of pulmonary hypertension and right-sided heart failure. Efficacy of specific interventions for this complication of CF has not been systematically assessed. Prompt treatment of airway symptoms and nocturnal oxygen supplementation or bilevel positive airway pressure support should be considered in selected cases.

Acute Respiratory Failure

Acute respiratory failure (see Chapter 71) rarely occurs in patients with mild to moderate lung disease and is usually the result of a severe viral or other infectious illness. Because patients with this complication can regain their previous status, intensive therapy is indicated. In addition to aerosol, postural drainage, and intravenous antibiotic treatment, oxygen is required to raise the arterial PaO_2. An increasing PCO_2 may require ventilatory assistance. Endotracheal or bronchoscopic suction may be necessary to clear airway inspissated secretions and can be repeated daily. Right-sided heart failure should be treated vigorously. Recovery is often slow. Intensive intravenous antibiotic therapy and postural drainage should be continued for 1-2 wk after the patient has regained baseline status.

Chronic Respiratory Failure

Patients with CF acquire chronic respiratory failure after prolonged deterioration of lung function. Although this complication can occur at any age, it is now seen most frequently in adult patients. Because a long-standing PaO_2 <50 mm Hg promotes the development of right-sided heart failure, patients usually benefit from low-flow oxygen to raise arterial PO_2 to ≥55 mm Hg. Increasing hypercapnia may prevent the use of optimal fraction of inspired oxygen. Most patients improve somewhat with intensive antibiotic and pulmonary therapy measures and can be discharged from the hospital. Low-flow oxygen therapy is needed at home, especially with sleep. Noninvasive ventilatory support can improve gas exchange and has been documented to enhance quality of life. Ventilatory support may be particularly useful for patients awaiting lung transplantation. These patients usually display cor pulmonale and should reduce their salt intake and be given diuretics. Caution should be exercised to avoid ventilation-suppressing metabolic alkalosis that results from CF-related chloride depletion and, in many cases, from diuretic-induced bicarbonate retention. Chronic pain (headache, chest pain, abdominal pain, and limb pain) is frequent at the end of life and responds to judicious use of analgesics, including opioids. Dyspnea has been ameliorated with nebulized fentanyl.

Lung transplantation is an option for end-stage lung disease (see Chapter 443) but a topic of vigorous debate. Criteria for referral continue to be a subject of investigation and ideally include estimates of longevity with and without transplant based on lung function and exercise tolerance data. Because of bronchiolitis obliterans (see Chapter 394.1) and other complications, transplanted lungs cannot be expected to function for the lifetime of a recipient, and repeat transplantation is increasingly common. The demand for donor lungs exceeds the supply, and waiting lists as well as duration of waits continue to grow. The protocol for matching donor organs with lung transplant recipients has been revised to account for the severity of the patients' lung disease. In a review of lung transplantation in children with CF between 1992 and 2002, pretransplantation colonization with *B. cepacia,* diabetes, and older age decreased posttransplantation survival. The review suggests that transplantation is often associated with many complications and may not prolong life nor significantly improve its quality.

Heart Failure

Some patients experience reversible right-sided heart failure (see Chapter 442) as the result of an acute event such as a viral infection or pneumothorax. Individuals with long-standing, advanced pulmonary disease, especially those with severe hypoxemia (PaO_2 <50 mm Hg), often acquire chronic right-sided heart failure. The mechanisms include hypoxemic pulmonary arterial constriction and loss of the pulmonary vascular bed. Pulmonary arterial wall changes contribute to increased vascular resistance with time. Evidence for concomitant left ventricular dysfunction is often found. Cyanosis, increased shortness of breath, increased liver size with a tender margin, ankle edema, jugular venous distention, an unusual weight gain, increased heart size seen on chest radiograph, or evidence for right-sided heart enlargement on electrocardiogram or echocardiogram helps to confirm the diagnosis. Diuresis induced by furosemide (1 mg/kg administered intravenously) confirms the suspicion of fluid retention. Repeated doses are often required at 24-48 hr intervals to reduce fluid accumulation and accompanying symptoms. Concomitant use of spironolactone may protect against potassium depletion and facilitate long-term diuresis. Hypochloremic alkalosis complicates the long-term use of

loop diuretics. Digitalis is not effective in pure right-sided failure but may be useful when there is an associated left-sided dysfunction. The arterial Po_2 should be maintained at >50 mm Hg if possible. Intensive pulmonary therapy, including intravenous antibiotics, is most important. Initially, the salt intake should be limited. Volume overload and antibiotics with high sodium content should be avoided. No clear-cut long-term benefit from pulmonary vasodilators has been demonstrated. The prognosis for heart failure is poor, but a number of patients survive for ≥5 yr after the appearance of heart failure. Heart-lung transplantation may be an option (see preceding section).

Nutritional Therapy

Up to 90% of patients with CF have loss of exocrine pancreatic function as well as inadequate digestion and absorption of fats and proteins. They require dietary adjustment, pancreatic enzyme replacement, and supplementary vitamins. In general, children with CF need to exceed the usual required daily caloric intake to grow. Daily supplements of the fat-soluble vitamins are required.

Diet

Historically, at the time of diagnosis many infants presented with nutritional deficits; this situation is changing because of newborn screening. Sometimes young infants with a history of wheezy breathing were often started on soy-protein formulas prior to their evaluation; they did not use this protein well and often acquired hypoproteinemia with anasarca. Although in the past a low-fat, high-protein, high-calorie diet was generally recommended for older children, it resulted in deficiencies of essential fatty acids and poor growth. With the advent of improved pancreatic enzyme products, increased amounts of fat in the diet are well tolerated and preferred.

Most individuals with CF have a higher-than-normal caloric need because of increased work of breathing and perhaps because of increased metabolic activity related to the basic defect. When anorexia of chronic infection supervenes, weight loss occurs. Encouragement to eat high-calorie foods is important, but weight gain is not generally realized unless lung infection is controlled. Weight stabilization or gain sometimes requires nocturnal feeding via nasogastric tube or percutaneous enterostomy or with short-term intravenous hyperalimentation. Not infrequently, parent–child interactions at feeding time are maladaptive, and behavioral interventions can improve caloric intake. Long-term benefits of these interventions include improved quality of life and psychologic well-being. In addition there is good correlation between improved body mass index and maintenance of FEV_1.

Recombinant growth hormone therapy (3 times per week) has improved nutritional outcomes, including positive effects on nitrogen balance and improved height and weight velocities.

Pancreatic Enzyme Replacement

Pancreatic exocrine replacement therapy given with ingested food reduces but does not fully correct stool fat and nitrogen losses. Enzyme dosage and product should be individualized for each patient. Enteric-coated, pH-sensitive enzyme microspheres are most often prescribed. Several strengths up to 25,000 IU of lipase/capsule are available. Administration of excessive doses has been linked to **colonic strictures** requiring surgery. Consequently, enzyme replacement should not exceed 2,500 lipase units/kg/meal in most circumstances. In general, infants need 2,000-4,000 lipase units per feeding, which is most easily given mixed with applesauce on a spoon. Snacks should also be covered. The dose of enzymes required usually increases with age, but some patients have lower requirements as teenagers and young adults. Some individuals require proton pump inhibitor therapy to correct acid pH in the duodenum which is due to lack of exocrine pancreatic secretions; neutralization of duodenal pH permits activation of enteric coated pancreatic exocrine replacement therapy granules.

Vitamin and Mineral Supplements

Because pancreatic insufficiency results in malabsorption of fat-soluble vitamins (A, D, E, K), vitamin supplementation is recommended. Several vitamin preparations containing all 4 vitamins for patients with CF are available. They should be taken daily. Replacement doses may be required when low serum levels are documented or the patient is symptomatic. Infants with zinc deficiency and an acrodermatitis enteropathica–like rash have been described. In addition, attention should be paid to iron status; in one study, almost 30% of children with CF had low serum ferritin concentrations.

TREATMENT OF INTESTINAL COMPLICATIONS

Meconium Ileus

When meconium ileus (see Chapter 102.1) is suspected, a nasogastric tube is placed for suction and the newborn is hydrated. In many cases, diatrizoate (Gastrografin) enemas with reflux of contrast material into the ileum not only confirm the diagnosis but have also resulted in the passage of a meconium plug and clearing of the obstruction. Use of this hypertonic solution requires careful correction of water losses into the bowel. Children in whom this procedure fails require operative intervention. Children who are successfully treated generally have a prognosis similar to that of other patients with severe CF mutations. Infants with meconium ileus should be treated as if they have CF until adequate diagnostic testing can be carried out.

Distal Intestinal Obstruction Syndrome (Meconium Ileus Equivalent) and Other Causes of Abdominal Symptoms

Despite appropriate pancreatic enzyme replacement, 2-5% of patients accumulate fecal material in the terminal portion of the ileum and in the cecum, which may result in partial or complete obstruction. For intermittent symptoms, pancreatic enzyme replacement should be continued or even increased, and stool softeners (polyethylene glycol [MiraLAX] or docusate sodium [Colace]) given. Increased fluid intake is also recommended. Failure to relieve symptoms signals the need for large-volume bowel lavage with a balanced salt solution containing polyethylene glycol taken by mouth or by nasogastric tube. When there is complete obstruction, a diatrizoate enema, accompanied by large amounts of intravenous fluids, can be therapeutic. Intussusception (see Chapter 333.3) and volvulus (see Chapter 329.4) must also be considered in the differential diagnosis. Intussusception, usually ileocolic, occurs at any age and often follows a 1-2 day history of "constipation." It can often be diagnosed and reduced via a diatrizoate enema. If a nonreducible intussusception or a volvulus is present, laparotomy is required. Repeated episodes of intussusception may be an indication for cecectomy.

Chronic appendicitis with or without periappendiceal abscess may manifest as recurrent or persistent abdominal pain, raising the question of need for a laparotomy. A lack of acid buffering in the duodenum appears to promote duodenitis and ulcer formation in some children. Other reasons for surgical procedures include carcinoma of the colon or biliary tract and sclerosing colonopathy.

Gastroesophageal Reflux

See Chapter 323.

Because several factors raise intraabdominal pressure, including cough and obstructed airways, pathologic gastroesophageal reflux is not uncommon and may exacerbate lung disease secondary to reflex wheezing and repeated aspiration. Dietary, positional, and medication therapies should be considered. Cholinergic agonists are contraindicated because they trigger mucus secretion and progressive respiratory difficulty. Reduction of stomach acid secretion can help, with proton pump inhibitors being the most effective agents. Fundoplication is a procedure of last resort.

Rectal Prolapse

See Chapter 344.5.

Though uncommon, rectal prolapse occurs most often in infants with CF, and less frequently in older children with the disease. It is usually related to steatorrhea, malnutrition, and repetitive cough. The prolapsed rectum can usually be replaced manually by continuous gentle pressure with the patient in the knee-chest position. Sedation

may be helpful. To prevent an immediate recurrence, the buttocks can be taped closed. Adequate pancreatic enzyme replacement, decreased fat and roughage in the diet, stool softener, and control of pulmonary infection result in improvement. Occasionally, a patient may continue to have rectal prolapse and may require sclerotherapy or surgery.

Hepatobiliary Disease

Liver function abnormalities associated with biliary cirrhosis can be improved by treatment with ursodeoxycholic acid. The ability of bile acids to prevent progression of cirrhosis has not been clearly documented. Portal hypertension with esophageal varices, hypersplenism, or ascites occurs in ≤8% of children with CF (see Chapter 367). The acute management of bleeding esophageal varices includes nasogastric suction and cold saline lavage. Sclerotherapy is recommended after an initial hemorrhage. In the past, significant bleeding has also been treated successfully with portosystemic shunting. Splenorenal anastomosis has been the most effective treatment. Pronounced hypersplenism may require splenectomy. Cholelithiasis should prompt surgical consultation. The management of ascites is discussed in Chapter 370.

Obstructive jaundice in newborns with CF needs no specific therapy. Hepatomegaly with steatosis requires careful attention to nutrition and may respond to carnitine repletion. Rarely, biliary cirrhosis proceeds to hepatocellular failure, which should be treated as in patients without CF (see Chapters 364 and 367). End-stage liver disease is an indication for liver transplantation in children with CF, especially if pulmonary function is good (see Chapter 368).

Pancreatitis

Pancreatitis can be precipitated by fatty meals, alcohol ingestion, or tetracycline therapy. Serum amylase and lipase values may remain elevated for long periods. Treatment of this disorder is discussed in Chapter 351.

Hyperglycemia

Onset of hyperglycemia occurs most frequently after the 1st decade. Approximately 20% of young adults are treated for hyperglycemia, although the incidence of CF-related diabetes may be up to 50% in CF adults. Prevalence is greater in females and in F508del homozygotes. Ketoacidosis is rarely encountered. The pathogenesis includes both impaired insulin secretion and insulin resistance. Routine screening consists of an annual modified 2-hr oral glucose tolerance test after the child reaches age 10 yr. Glucose intolerance without urine glucose losses is usually not treated; glycosylated hemoglobin levels should be followed at least annually. With persistent glucosuria and symptoms, insulin treatment should be instituted. Oral hypoglycemic agents, with or without drugs that reduce insulin resistance, may also be effective. Exocrine pancreatic insufficiency and malabsorption make strict dietary control of hyperglycemia difficult. Corticosteroid therapy should be avoided. The development of significant hyperglycemia favors acquisition of *P. aeruginosa* and *B. cepacia* in the airways and may adversely affect pulmonary function. Thus, careful control of blood glucose level is an important goal. Long-term vascular complications of diabetes can occur, providing an additional rationale for good control of blood glucose levels.

OTHER THERAPY

Nasal Polyps

Nasal polyps (see Chapter 378) occur in 15-20% of patients with CF and are most prevalent in the 2nd decade of life. Local corticosteroids and nasal decongestants occasionally provide some relief. When the polyps completely obstruct the nasal airway, rhinorrhea becomes constant, or widening of the nasal bridge is noticed, surgical removal of the polyps is indicated; polyps may recur promptly or after a symptom-free interval of months to years. Polyps inexplicably stop developing in many adults.

Rhinosinusitis

Opacification of paranasal sinuses is not an indication for intervention. Acute or chronic sinus-related symptoms are treated initially with antimicrobials, with or without maxillary sinus aspiration for culture. Functional endoscopic sinus surgery has anecdotally provided benefit.

Salt Depletion

Salt losses from sweat in patients with CF can be high, especially in warm arid climates. Children should have free access to salt, and precautions against overdressing infants should be observed. Salt supplements are often prescribed to newborns identified through newborn screening and to children who live in hot weather climates. Hypochloremic alkalosis should be suspected in any infant who has had symptoms of gastroenteritis, and prompt fluid and electrolyte therapy should be instituted as needed.

Growth and Maturation

Delayed growth should be vigorously addressed by enhancing nutrition, treating lung disease more vigorously, and, in selected instances, endocrine evaluation and, possibly, growth hormone therapy. The risk: benefit ratio for anabolic steroid therapy does not support its use for undersized children with CF. Delayed sexual maturation, often associated with short stature, occurs fairly frequently in children with CF. Although many patients have severe pulmonary infection or poor nutrition, delayed puberty also occurs in those with otherwise mild disease and is not well explained. Adolescents with CF should receive specific counseling throughout their developing years concerning sexual maturation and reproductive potential.

Surgery

Minor surgical procedures, including dental work, should be performed with the use of local anesthesia if possible in children with CF. Patients with good or excellent pulmonary status can tolerate general anesthesia without any intensive pulmonary measures before the procedure. Those with moderate or severe pulmonary infection usually do better with a 1-2 wk course of intensive antibiotic treatment and increased airway clearance before surgery. If this approach is impossible, prompt intravenous antibiotic therapy is indicated once it is recognized that major surgery is required. The total time of anesthesia should be kept to a minimum. After induction, tracheal suctioning is useful and should be repeated. Patients with severe disease require monitoring of blood gas values and may need ventilatory assistance in the immediate postoperative period.

After major surgery, cough should be encouraged and airway clearance treatments should be re-instituted as soon as possible, usually within 24 hr. Adequate analgesia is important if early effective therapy is to be achieved. For those with significant pulmonary involvement, intravenous antibiotics are continued for 7-14 days postoperatively. Early ambulation and intermittent deep breathing are important; an incentive spirometer can also be helpful. After open thoracotomy for treatment of pneumothorax or lobectomy, the chest tube is the greatest single obstacle to effective pulmonary therapy and should be removed as soon as possible so that full postural drainage therapy can resume.

PROGNOSIS

CF remains a life-limiting disorder, although survival has improved dramatically in the past 30-40 yr. Infants with severe lung disease occasionally succumb, but most children survive this difficult period and are relatively healthy into adolescence or adulthood. The slow progression of lung disease eventually reaches disabling proportions. Life table data now indicate a median cumulative survival of 37 yr. Male survival is somewhat better than female survival for reasons that are not readily apparent. Children in socioeconomically disadvantaged families have, on average, a poorer prognosis.

Children with CF usually have good school attendance records and should not be restricted in their activities. A high percentage eventually attend and graduate from college. Most adults with CF find satisfactory employment, and an increasing number marry. Transitioning care from pediatric to adult care centers by 21 yr of age is an important objective and requires a thoughtful, supportive approach involving both the pediatric and internal medicine specialists.

With increasing life span for patients with CF, a new set of psychosocial considerations has emerged, including dependence-independence issues, self-care, peer relationships, sexuality, reproduction, substance abuse, educational and vocational planning, medical care costs and other financial burdens, and anxiety concerning health and prognosis. Many of these issues are best addressed in an anticipatory fashion, before the onset of psychosocial dysfunction. With appropriate medical and psychosocial support, children and adolescents with CF generally cope well. Achievement of an independent and productive adulthood is a realistic goal for many.

Chapter 404

Primary Ciliary Dyskinesia (Immotile Cilia Syndrome, Kartagener Syndrome)

Thomas W. Ferkol Jr.

Primary ciliary dyskinesia (PCD) is an inherited disorder characterized by impaired ciliary function leading to diverse clinical manifestations, including chronic sinopulmonary disease, persistent middle ear effusions, laterality defects, and infertility. Although the estimated frequency of PCD is 1 in 12,000 to 1 in 20,000 live births, its prevalence in children with repeated respiratory infections has been estimated to be as high as 5%.

NORMAL CILIARY ULTRASTRUCTURE AND FUNCTION

Three types of cilia exist in the humans: motile cilia; primary (sensory) cilia; and nodal cilia.

Motile cilia are hair-like organelles that move fluids, mucous, and inhaled particulates vectorially from conducting airways, paranasal sinuses, and eustachian tubes. The upper and lower respiratory tracts are continuously exposed to inhaled pathogens, and local defenses have evolved to protect the airway. The respiratory epithelium in the nasopharynx, middle ear, paranasal sinuses, and larger airways are lined by a ciliated, pseudostratified columnar epithelium that is essential for mucociliary clearance (Fig. 404-1). A mature ciliated epithelial cell has approximately 200 uniform motile cilia that are anatomically and functionally oriented in the same direction, moving with intracellular and intercellular synchrony. Anchored by a basal body to the apical cytoplasm and extending from the apical cell surface into the airway lumen, each cilium is a complex, specialized structure, composed of hundreds of proteins. It contains a cylinder of microtubule doublets organized around a central pair of microtubules (Fig. 404-2), leading to the characteristic “9+2” arrangement seen on cross-sectional views on transmission electron microscopy. A membrane continuous

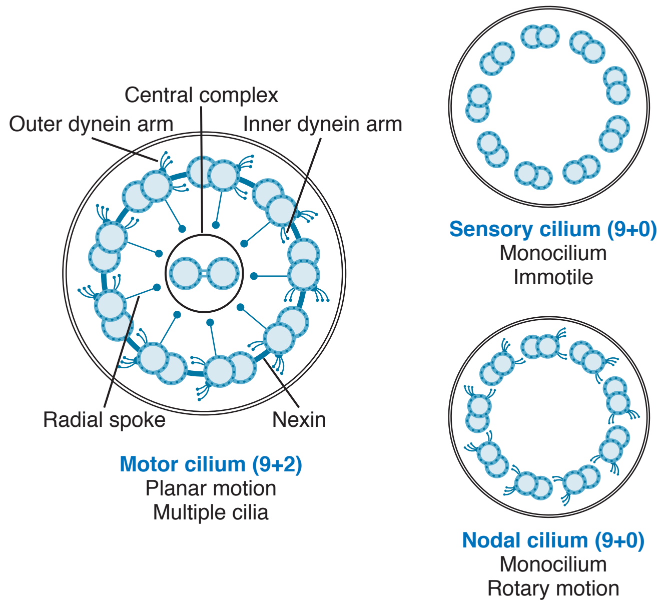

Figure 404-2 Schemata showing the 3 general classes of normal cilia (motile “9+2,” motile “9+0,” and nonmotile “9+0”), which demonstrate the complex structure and arrangement of the ciliary axoneme.

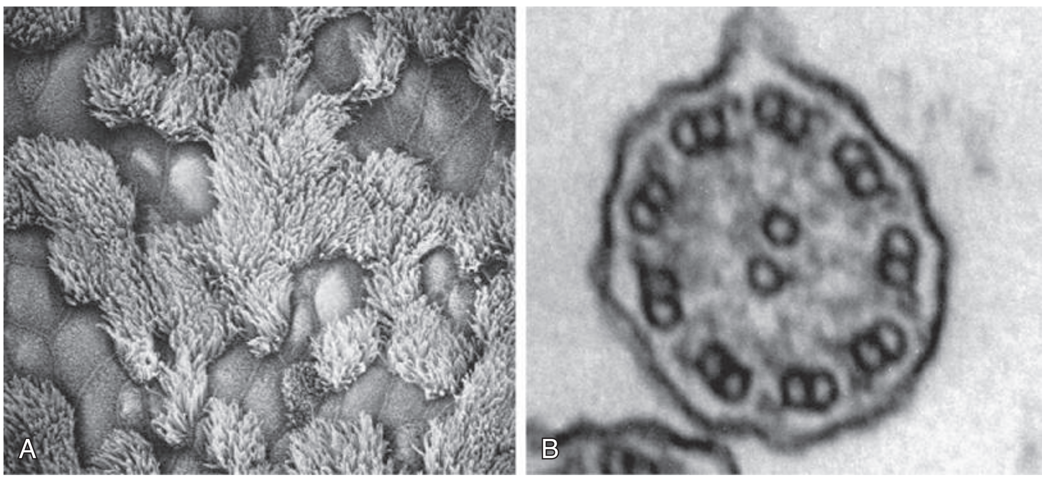

Figure 404-1 Electron photomicrographs showing **(A)** an airway epithelium grown in primary culture, showing ciliated and non-ciliated cells, and **(B)** a normal motor cilium.

with the plasma membrane covers the central fibrillar structure, or axoneme. The ciliary axoneme is highly conserved across species, and the structural elements of simple protozoan flagella and the mammalian cilium are similar. Attached to the A microtubules as distinct inner and outer dynein arms, multiple different adenosine triphosphatases, called **dyneins**, serve as "motors" of the cilium and promote microtubule sliding, which is converted into bending. The inner dynein arm influences the bend shape of the cilium, whereas the outer dynein arm controls beat force and frequency. Nexin links connect adjacent outer microtubular doublets limit the degree of sliding between microtubules, and with the radial spokes are controlled by the dynein regulatory complex. The result is a ciliary stroke and coordinated beating at a frequency constant throughout the airway, 8-20 beats/sec, but can be negatively affected by several factors, such as anesthetics and dehydration. Alternatively, beat frequency may be accelerated by exposure to irritants or bioactive molecules, including β-adrenergic agents, acetylcholine, and serotonin. Cilia beat frequency can be increased through the activity of nitric oxide synthases that are localized in the apical cytoplasm. The coordinated wave-like pattern of ciliary motion has important functions in fluid and cell movement, and any disturbance in the precise, orchestrated movement of the cilia can lead to disease.

Primary (sensory) cilia are present during interphase on most cell types. These cilia lack a central microtubule doublet and dynein arms, thus creating a "9+0" arrangement and leaving them immotile (see Fig. 404-2). For years, these structures were considered nonfunctional vestigial remnants, but primary cilia are important signaling organelles that sense the extracellular environment. They are mechanoreceptors, chemosensors, osmosensors, and, in specialized cases, defect changes in light, temperature, and gravity. Primary cilia are found on the surface of nondividing cells, including the renal nephron, bile ductules, chondrocytes, astrocytes, and cells in sensory organs. Defects are linked to wide-ranging pediatric conditions, such as various polycystic kidney diseases, nephronophthisis, Bardet-Biedl syndrome, Meckel-Gruber syndrome, Joubert syndrome, Alström syndrome, Ellis-van Creveld syndrome, and Jeune thoracic dystrophy.

The third distinct classification of cilia exists only during a brief period of embryonic development. These **nodal cilia** have a "9+0" microtubule arrangement similar to that of primary cilia, but they exhibit a whirling, rotational movement (see Fig. 404-2), resulting in leftward flow of extracellular fluid that establishes body sidedness. Nodal cilia defects result in body orientation abnormalities, such as **situs inversus totalis**, **situs ambiguus**, and **heterotaxy** associated with congenital heart disease, asplenia, and polysplenia (see Chapter 431.11).

GENETICS OF PRIMARY CILIARY DYSKINESIA

PCD is typically has autosomal recessive patterns of inheritance, although rare cases of autosomal dominant and X-linked inheritance have been reported. PCD is a genetically heterogeneous disorder involving multiple genes; mutations in any protein that is involved in ciliary assembly, structure, or function could theoretically cause disease. Early linkage analyses showed substantial locus heterogeneity, which made correlations between ciliary defects and the underlying mutations difficult. Numerous PCD-associated genes have been discovered. The advent of high-throughput sequencing technologies has allowed for even more rapid identification of new mutations in PCD subjects. To date, mutations in 18 different genes have been linked to PCD (Fig. 404-3), including those that encode proteins integral to the outer dynein arm (*DNAH5, DNAI1, DNAL1, DNAI2, TXNDC3,* and *DNAH11*), inner dynein arm and axonemal organization (*CCDC39* and *CCDC40*), and the central apparatus and radial spokes (*RSPH9, RSPH4A,* and *HYDIN*). More recently, mutations in genes that code for cytoplasmic proteins involved in cilia assembly or protein transport (*HEATR2, DNAAF1, DNAAF2, DNAAF3, CCDC103, LRRC6,* and *CCDC114*) have been shown to cause ultrastructural abnormalities. The genetics of PCD has further exposed the gaps in current diagnostic approaches. For instance, *DNAH11* mutations have been shown to cause typical clinical phenotypes without apparent axonemal ultrastructural defects or reduced ciliary beat frequency. Mutations in 2 other genes, *CCDC39* and *CCDC40,* produce inconsistent structural abnormalities characterized by disordered microtubules in some, but not all, cilia, which underscores the observation that current diagnostic testing will miss cases.

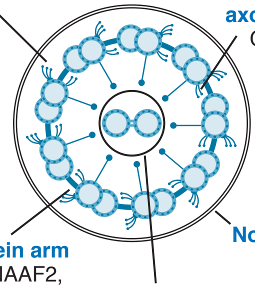

Figure 404-3 Classification of proteins mutated in primary ciliary dyskinesia. *(Adapted from Horani A, Ferkol TW: Molecular genetics of primary ciliary dyskinesia. In* Encyclopedia of Life Sciences *(eLS), 2014. John Wiley & Sons, Chichester, UK. Available at:* http://www.els.net/WileyCDA/ElsArticle/refId-a0024989.html.*)*

Table 404-1 Clinical Manifestations of Primary Ciliary Dyskinesia

RESPIRATORY TRACT	GENITOURINARY TRACT
Lung Neonatal respiratory distress Chronic cough Recurrent pneumonia Bronchiectasis *Middle Ear* Chronic otitis media Conductive hearing loss *Paranasal Sinuses* Neonatal rhinitis Chronic mucopurulent rhinitis Chronic pansinusitis Nasal polyposis	Male and female infertility LEFT-RIGHT ORIENTATION DEFECTS Situs inversus Heterotaxy Congenital heart disease CENTRAL NERVOUS SYSTEM Hydrocephalus Retinitis pigmentosa

CLINICAL MANIFESTATIONS OF PRIMARY CILIARY DYSKINESIA

See Table 404-1.

Most patients with PCD present with **neonatal respiratory distress**, which is manifested as tachypnea, hypoxemia, or even respiratory failure requiring mechanical ventilation. The association of respiratory distress in term neonates with PCD has been underappreciated. The upper respiratory tract is almost universally involved in PCD, and **persistent rhinosinusitis** is common during infancy. Inadequate innate mucus clearance leads to chronic sinusitis (see Chapter 380) and nasal polyposis. Middle ear disease occurs in nearly all children with PCD, with varying degrees of **chronic otitis media** leading to conductive hearing loss and myringotomy tube placement, which is often complicated by intractable otorrhea.

Impaired mucociliary clearance of the lower respiratory tract leads to daily productive cough, often in young children, secondary to chronic bronchitis. Bacterial cultures of sputum or lavage fluid frequently yield nontypeable *Haemophilus influenzae* (see Chapter 194), *Staphylococcus aureus* (see Chapter 181.1), *Streptococcus pneumoniae* (see Chapter 182), and *Pseudomonas aeruginosa* (see Chapter 205.1). Persistent airway infection and inflammation lead to **bronchiectasis**,

even in preschool children. Clubbing is a sign of long-standing pulmonary involvement.

Left-right laterality defects (e.g., *situs inversus totalis*) are found in half of all children with PCD. Without functional nodal cilia in the embryonic period, thoracoabdominal orientation is random. These patients have **Kartagener triad**, defined as *situs inversus totalis*, chronic sinusitis, and bronchiectasis. Approximately 25% of patients with *situs inversus totalis* have PCD, so *situs inversus totalis* alone does not establish the diagnosis of PCD. Other laterality defects, such as heterotaxy, are associated with PCD and may coexist with congenital cardiac defects, asplenia, or polysplenia.

Most men with PCD have dysmotile spermatozoa because flagellar and ciliary ultrastructure is similar. Male infertility is typical, but not always found in this disease. Fertility issues in women have also been reported and are likely a result of ciliary dysfunction in the fallopian tubes.

A few case reports have associated **neonatal hydrocephalus** with PCD. The ependyma of the brain ventricles are lined by ciliated epithelium and are important for cerebrospinal fluid flow through the ventricles and aqueduct of Sylvius. The finding of enlarged brain ventricles on sonograms, when linked with *situs inversus totalis,* has been proposed as a prenatal diagnostic marker for PCD. X-linked retinitis pigmentosa has been associated with recurrent respiratory infections in families with *RPGR* gene mutations. Intraflagellar transport proteins are essential for photoreceptor assembly, and when mutated, lead to apoptosis of the retinal pigment epithelium (see Chapter 630).

Table 404-2 Electron Microscopic Findings in Primary Ciliary Dyskinesia vs Acquired Cilia Abnormality

	PCD	ACQUIRED DEFECTS
EM ultrastructure	Dynein arm deficiency Outer arms Inner arms Both Translocation of central tubules Few or absent cilia (generalized)	Compound cilia Added peripheral tubules Deleted peripheral tubules Added central pairs Translocation of central tubules Few or absent cilia (patchy)
Beat frequency	Hyperkinetic, slow or absent	May be normal or reduced
Wave form	Abnormal	May be normal or abnormal

EM, electron microscopy; PCD, primary ciliary dyskinesia.

From Stillwell PC, Wartchow EP, Sagel SD. Primary ciliary dyskinesia in children: A review for pediatricians, allergists, and pediatric pulmonologists. Pediatr Allergy Immunol Pulmonol *24: 191–196, 2011, Table 1.*

DIAGNOSIS OF PRIMARY CILIARY DYSKINESIA

The diagnosis of PCD should be suspected in children with chronic or recurring upper and lower respiratory tract symptoms that begin in early infancy and is currently based on the presence of characteristic clinical phenotype and ultrastructural defects of cilia, though this approach will miss affected individuals. The diagnosis is often delayed, even in children who have classic clinical features, such as chronic rhinosinusitis in infancy, persistent otitis media, or even *situs inversus totalis*. The average age at PCD diagnosis is approximately 4 yr; a high index of suspicion is necessary.

Imaging studies show extensive involvement of the paranasal sinuses. Chest radiographs frequently demonstrate bilateral lung overinflation, peribronchial infiltrates, and lobar atelectasis. Computerized x-ray tomography of the chest often reveals bronchiectasis, often involving the anatomic right middle lobe or lingual, even in young children. *Situs inversus totalis* in a child who has chronic respiratory tract symptoms is highly suggestive of PCD, but this configuration occurs in only half of patients with PCD. Pulmonary function testing typically shows progressive intrathoracic airway obstruction.

Transmission electron microscopy is the current gold standard to assess structural defects within the cilium. Curettage from the nasal epithelium or endobronchial brushing can provide an adequate specimen for review. Identification of a discrete, consistent defect in any aspect of the ciliary structure with concurrent phenotypic features is sufficient to make the diagnosis. Shortening or absence of dynein arms is the most common abnormality seen in PCD, accounting for 90% of cases with defined ultrastructural defects (see Fig. 404-3). Other axonemal changes consistent with PCD include microtubular transposition, radial spoke and nexin link defects, and ciliary agenesis. Unfortunately, ultrastructural examination of cilia as a diagnostic test for PCD has significant drawbacks. First, the absence of axonemal defects does not exclude PCD; nearly 30% of all affected individuals have normal ciliary ultrastructure. Careful interpretation of the ultrastructural findings is necessary, because nonspecific changes may be seen in relation to exposure to environmental pollutants or infection. Ciliary defects can be acquired (Table 404-2). Acute airway infection or inflammation can result in structural changes (e.g., compound cilia or blebs). Ciliary disorientation has been proposed as a form of PCD, but this phenomenon is the result of airway injury. Frequently, the diagnosis of PCD can be delayed or missed because of inadequate tissue collection or sample processing as well as the lack of an experienced pathologist who can distinguish between primary and acquired ciliary defects. Several reviews have advocated culturing of airway epithelial cells and allowing the secondary changes to resolve.

Qualitative tests to assess ciliary function have been used to screen for PCD. Ciliary beat frequency measurements that use conventional microscopic techniques have been used as a screen, but this method alone will miss cases of PCD. Cilia inspection using standard light microscopy is insufficient to support or exclude the diagnosis. High-resolution, high-speed, digital imaging of ciliary motion in multiple planes has permitted comprehensive analysis of abnormal beat patterns. This approach is available only at a limited number of clinical centers and requires sophisticated software and expertise. Immunofluorescence imaging has been used to show mislocalization of dynein arm proteins. Such techniques are research tools and not widely available.

Another promising approach has exploited the observation that nasal nitric oxide concentrations are reduced in subjects with PCD. Because nasal nitric oxide measurements are relatively easy to perform and noninvasive, this method is a promising screen and potentially a diagnostic test for PCD, provided that cystic fibrosis has been excluded (see Chapter 403). Few studies in younger children have been reported, and the accuracy of nasal nitric oxide measurements in infants has not been established.

PCD is highly heterogenic owing to the large number of proteins involved in cilia assembly and function. Recent advances in gene sequencing techniques have led to the identification of a growing number of PCD-associated genes. The pace of new gene discovery has accelerated during the past 2 yr, and new discoveries are forthcoming. Genetic testing for PCD is available, but commercial laboratories offer testing for only some mutations. It is reasonable to expect that genetic testing will become the preferred diagnostic approach for PCD, but disease-causing mutations have only been linked to approximately 60% of known cases.

TREATMENT

No therapies correct ciliary dysfunction in PCD. Many of the treatments applied to PCD patients are similar to those used in other suppurative lung diseases characterized by impaired airway clearance and bronchiectasis, such as cystic fibrosis, but none have been adequately studied to demonstrate their efficacy in PCD.

Strategies to enhance mucociliary clearance are central to PCD therapy, and routine airway clearance techniques using postural

drainage, percussion vests, positive expiratory pressure devices, or other techniques should be instituted on a daily basis. Because ciliary function is impaired, cough becomes a critical mechanism for mucus clearance and should not be suppressed. Exercise can enhance airway clearance in patients with PCD and should be encouraged. Inhaled mucolytic agents are often used in cystic fibrosis care, and few case reports have shown improvement in lung function in patients with PCD after treatment.

When children with PCD develop increasing respiratory symptoms consistent with infection, antimicrobial therapy should be instituted on the basis of respiratory culture results and bacterial sensitivities. Early eradication strategies to clear bacteria from the PCD lung have not been studied. Maintenance therapy with inhaled or oral antibiotics can be used cautiously in patients with PCD who have bronchiectasis or frequent exacerbations, although current literature lacks evidence supporting long-term antimicrobial therapy. Immunizations against pertussis, influenza, and pneumococci are cornerstones of care. Additional preventive measures include avoidance of cigarette smoke and other airway irritants.

Although β-adrenergic agonists increase ciliary beat frequency in normal epithelial cells, data is lacking that shows these agents improve function of dyskinetic cilia. Moreover, they do not necessarily provide bronchodilation in patients with PCD and obstructive airway disease.

Surgical resection of bronchiectatic lung has been performed on patients with PCD, typically in cases of localized disease with severe hemoptysis or recurrent febrile illnesses. It is unclear whether surgical interventions provide reduction in symptoms or survival benefit.

Progression to end-stage lung disease and respiratory failure has been reported in patients with PCD. Adult patients have undergone successful heart-lung, double lung, or living donor lobar lung transplantation. *Situs inversus totalis* complicates the procedure owing to anatomic considerations. Otherwise, survival is similar to that for other transplant recipients.

Treatment of chronic otitis media and middle ear effusions in patients with PCD is controversial. Myringotomy tubes are frequently placed in affected children, but they are not without complications, because they may lead to chronic mucoid otorrhea, tympanosclerosis, and permanent membrane perforation. Myringotomy tubes have not measurably improved hearing acuity. Although hearing tends to improve with time, it should be routinely screened and hearing aids used when necessary.

Chronic rhinitis and sinusitis are frequent clinical manifestations of PCD. No treatments have been shown to be effective, although patients are often treated with nasal washes, paranasal sinus lavage, and systemic antibiotics when they are symptomatic. As with any overuse of antimicrobial agents, the development of resistant organisms is a concern. When nasal symptoms are severe or refractory to medical management, endoscopic sinus surgery can be used to promote drainage or local delivery of medications, though the benefit may be short-lived.

PROGNOSIS

Although signs and symptoms related to upper respiratory involvement predominate early in PCD, clinical manifestations of lower respiratory tract disease tend to increase with age and become the leading cause of morbidity and mortality in PCD patients. It is believed that progression and extent of lung disease can be slowed with early diagnosis and therapy. Thus, routine surveillance studies recommended for the care of children with PCD include (1) regular spirometry to monitor pulmonary function, (2) chest imaging, and (3) sputum or oropharyngeal cultures to assess lung respiratory flora.

Patients with PCD typically have slower decline in pulmonary function than those with cystic fibrosis. Its prognosis and long-term survival are better. Many patients with PCD have a normal or near-normal life span, although some do experience progressive bronchiectasis and respiratory deterioration earlier in life.

Diffuse Lung Diseases in Childhood

See also Chapter 399.

405.1 Inherited Disorders of Surfactant Metabolism

Lawrence M. Nogee, F. Sessions Cole III, and Aaron Hamvas

Pulmonary surfactant is a mixture of phospholipids and proteins synthesized, packaged, and secreted by alveolar type II pneumocytes (AEC2s) that line the distal air spaces. This mixture forms a monolayer at the air–liquid interface that lowers surface tension at end-expiration of the respiratory cycle, preventing atelectasis and ventilation–perfusion mismatch. Four surfactant-associated proteins have been described: surfactant proteins A and D (SP-A, SP-D) participate in host defense in the lung, whereas surfactant proteins B and C (SP-B, SP-C) contribute to the surface tension–lowering activity of the pulmonary surfactant. The adenosine triphosphate–binding cassette protein member A3, ABCA3, is a transporter located on the limiting membrane of lamellar bodies, the storage organelle for surfactant within alveolar type II cells, and has an essential role in surfactant phospholipid metabolism. The proper expression of the surfactant proteins and ABCA3 is dependent on a number of transcription factors, particularly thyroid transcription factor 1 (TTF-1). Two genes for SP-A *(SFTPA1, SFTPA2)* and 1 gene for SP-D *(SFTPD)* are located on human chromosome 10, whereas single genes encode SP-B *(SFTPB),* SP-C *(SFTPC),* TTF-1 *(NKX2-1)* and ABCA3 *(ABCA3),* which are located on human chromosomes 2, 8, 14, and 16, respectively. Inherited disorders of SP-B, SP-C, ABCA3 and TTF-1 have been identified in humans and are collectively termed **surfactant dysfunction disorders** (Table 405-1).

PATHOLOGY

Histopathologically, these disorders share a unique constellation of features, including AEC2 hyperplasia, alveolar macrophage accumulation, interstitial thickening and inflammation, and alveolar proteinosis. A number of different descriptive terms have historically been applied to these disorders, including ones borrowed from adult forms of interstitial lung disease (**desquamative interstitial pneumonia**, nonspecific interstitial pneumonia) as well as a disorder unique to infancy (**chronic pneumonitis of infancy**). These diagnoses in infants and children are strongly indicative of surfactant dysfunction disorders but do not distinguish which gene is responsible. As the prognosis and inheritance patterns differ depending upon the gene involved, genetic testing should be offered when one of these conditions is reported in the lung biopsy or autopsy of a child.

Deficiency of Surfactant Protein B (Surfactant Metabolism Dysfunction, Pulmonary, 1; SMDP1; OMIM #265120)

Clinical Manifestations

Infants with an inherited deficiency of SP-B present in the immediate neonatal period with respiratory failure. This autosomal recessive disorder is clinically and radiographically similar to the respiratory distress syndrome (RDS) of premature infants (see Chapter 101.3) but typically affects full-term infants. The initial degree of respiratory distress is variable, but the disease is progressive and is refractory to mechanical ventilation, surfactant replacement therapy, glucocorticoid

Table 405-1 Comparison of Surfactant Deficiency Syndromes

	SP-B DEFICIENCY	SP-C DISEASE	ABCA3 DEFICIENCY	TTF-1 DEFICIENCY
Gene name	*SFTPB*	*SFTPC*	*ABCA3*	*NKX2-1*
Age of onset	Birth	Birth–adulthood	Birth–childhood	Birth–childhood
Inheritance	Recessive	Dominant/sporadic	Recessive	Sporadic/dominant
Mechanism	Loss of function	Gain of toxic function or dominant negative	Loss of function	Loss of function ?Gain of function
Natural history	Lethal	Variable	Generally lethal, may be chronic	Variable
Diagnosis:				
Biochemical *(tracheal aspirate)*	Absence of SP-B and presence of proSP-C	None	None	None
Genetic *(DNA)*	Sequence *SFTPB*	Sequence *SFTPC*	Sequence *ABCA3*	Sequence *NKX2-1;* deletion analysis
Ultrastructural *(lung biopsy–electron microscopy)*	Disorganized lamellar bodies	Not specific; may have dense aggregates	Small dense lamellar bodies with eccentrically placed dense cores	Variable
Treatment	Lung transplantation or compassionate care	Supportive care, lung transplantation if progressing	Consider lung transplantation	Supportive care; treat coexisting conditions (hypothyroidism)

SP, surfactant protein.

administration, and extracorporeal membrane oxygenation. SP-B deficiency is recognized in diverse racial and ethnic groups. Almost all affected patients have died without lung transplantation, but prolonged survival is possible in cases of partial deficiency of SP-B. Although murine lineages heterozygous for SP-B deficiency are susceptible to oxidant injury and pulmonary infection, humans heterozygous for loss-of-function mutations in *SFTPB* are clinically normal as adults but may be at increased risk for obstructive lung disease if they also have a history of smoking.

Genetics

Multiple loss-of-function mutations in *SFTPB* have been identified. The most common is a net 2 base-pair insertion in codon 121 (originally termed 121ins2) that results in a frameshift, an unstable SP-B transcript, and absence of SP-B protein production. This mutation has accounted for 60-70% of the alleles found to date in patients identified with SP-B deficiency. Most other mutations have been family specific. A large deletion encompassing 2 exons of the SP-B gene has also been reported.

Diagnosis

A rapid, definitive diagnosis can be established with sequence analysis of *SFTPB,* which is available through clinical laboratories (http://www.genetests.org). In families in which a mutation was previously identified, antenatal diagnosis can be established by molecular assays of DNA from chorionic villous biopsy or amniocytes, which permits advanced planning of a therapeutic regimen. Other laboratory tests remain investigational, including analysis of tracheal effluent by for the presence or absence of SP-B protein and for incompletely processed precursor proSP-C peptides that have been found in SP-B–deficient human infants and animals. Immunostaining of lung biopsy tissue for the surfactant proteins can also support the diagnosis, although immunohistochemical assays for SP-B and SP-C are also generally available only on a research basis. Staining for SP-B is usually absent, but robust extracellular staining for proSP-C because of incompletely processed proSP-C peptides is observed and is diagnostic for SP-B deficiency. Such studies require a lung biopsy in a critically ill child but may be performed on lung blocks acquired at the time of autopsy, allowing for retrospective diagnosis. With electron microscopy, a lack of tubular myelin, disorganized lamellar bodies, and an accumulation of abnormal-appearing multivesicular bodies, suggest abnormal lipid packaging and secretion.

Surfactant Protein C Gene Abnormalities (Surfactant Metabolism Dysfunction, Pulmonary, 2; SMDP2; OMIM #610913)

SP-C is a very low-molecular-weight, extremely hydrophobic protein that, along with SP-B, enhances the surface tension–lowering properties of surfactant phospholipids. It is derived from proteolytic processing of a larger precursor protein (proSP-C).

Clinical Manifestations

The clinical presentation of patients with *SFTPC* mutations is quite variable. Some patients present at birth with symptoms, signs, and radiographic findings typical of RDS. Others present later in life, ranging from early infancy until well into adulthood, with gradual onset of respiratory insufficiency, hypoxemia, failure to thrive, and chest radiograph demonstration of interstitial lung disease, or, in the 5th or 6th decade of life, as pulmonary fibrosis. The age and severity of disease vary even within families with the same mutation. The natural history is also quite variable, with some patients improving either spontaneously or as the result of therapy, some with persistent respiratory insufficiency, and some progressing to the point of requiring lung transplantation. This variability in severity and course of the disease does not appear to correlate with the specific mutation and also hinders accurate assessment of prognosis.

Genetics

Multiple mutations in *SFTPC* have been identified in association with acute and chronic lung disease in patients ranging in age from newborn to adult. A mutation on only 1 *SFTPC* allele is sufficient to cause disease. Approximately half of these mutations arise spontaneously, resulting in sporadic disease, but the remainder are inherited as a dominant trait. A threonine substitution for isoleucine in codon 73 (termed p.I73T or p.Ile73Thr) accounts for 25-35% of the cases identified to date. Mutations in *SFTPC* are thought to result in production of misfolded proSP-C that accumulates within the alveolar type II cell and causes cellular injury, or alters the normal intracellular routing of proSP-C. The frequency of mutations or disease caused by mutations in *SFTPC* is unknown but is probably low. Mutations have been identified in diverse racial and ethnic groups.

Diagnosis

Sequencing of *SFTPC,* the only definitive diagnostic test, is available in clinical laboratories. The relatively small size of the gene facilitates such

analyses, which are quite sensitive, but because most *SFTPC* mutations are missense mutations, distinguishing true disease-causing mutations from rare yet benign sequence variants may be difficult. Immunostaining of lung tissue may demonstrate proSP-C aggregates but is available only on a research basis.

Disease Caused by Mutations in ABCA3 (Surfactant Metabolism Dysfunction, Pulmonary, 3; SMDP3; OMIM #610921)

Clinical Manifestations

Lung disease caused by mutations in *ABCA3* generally presents as either a severe, lethal form that manifests in the immediate newborn period clinically similar to SP-B deficiency, or a chronic form that appears most typically in the 1st yr of life with interstitial lung disease similar to SP-C–associated disease. Infants who are homozygous or compound heterozygous for null mutations, that is, the mutation is predicted to result in absence of protein expression, typically present with lethal neonatal disease, whereas infants with other types of mutations have more variable age of onset and outcomes. Heterozygosity for an *ABCA3* mutation may contribute to the severity of RDS in prematurely born infants, who, in contrast to ABCA3-deficient infants with mutations on both alleles, may eventually completely recover from their initial lung disease.

Genetics

Recessive mutations in *ABCA3* were first described in infants who presented with lethal respiratory distress in the newborn period, but now have been identified in older infants and children with interstitial lung disease. There is considerable allelic heterogeneity: More than 200 mutations scattered throughout the gene have been identified, most of which are family specific. A missense mutation that results in a valine substitution for glutamine in codon 292 (p.E292V or p.Glu292Val) in association with a second *ABCA3* mutation has been found in children with severe neonatal respiratory failure and in older children with interstitial lung disease and is present in approximately 0.4% of the general population. *ABCA3* mutations have been identified in diverse racial and ethnic groups. The precise frequency of disease is unknown, but large-scale sequencing projects indicate that the overall carrier rate for *ABCA3* mutations may be as high as 1 in 50 to 1 in 70 individuals. ABCA3 deficiency may thus contribute to a substantial proportion of **unexplained fatal lung disease** in term infants and of **interstitial lung disease** in older children.

Diagnosis

Sequence analysis of *ABCA3* is available in clinical laboratories and is the most definitive approach for diagnosis. Considerable variation in *ABCA3* necessitates careful interpretation regarding the functionality of an individual variant and its contribution to the clinical presentation. Additionally, sequence analysis is not 100% sensitive as functionally significant mutations may exist in untranslated regions that are not generally analyzed. In these situations, lung biopsy with electron microscopy to examine lamellar body morphology may be a useful adjunct to the diagnostic approach. Small lamellar bodies that contain electron-dense inclusions may be observed in association with *ABCA3* mutations. These findings support the hypothesis that ABCA3 function is necessary for lamellar body biogenesis. There are no biochemical markers to establish the diagnosis.

Disease Caused by Mutations in *NKX2-1* (Thyroid Transcription Factor 1, Choreoathetosis, Hypothyroidism, and Neonatal Respiratory Distress, OMIM #600635)

Clinical Manifestations

A large deletion of the region of chromosome 14 (14q13.3) encompassing the *NKX2-1* locus was first recognized in an infant with hypothyroidism and neonatal RDS. Since then, multiple large deletions involving the *NKX2-1* locus and contiguous genes as well as missense, frameshift, nonsense, and small insertion or deletion mutations scattered throughout the gene have been reported in individuals with hypothyroidism, lung disease, and neurologic symptoms, including benign familial chorea. Manifestation of dysfunction in all 3 organ systems has been referred to as **brain-thyroid-lung syndrome**, but disease may manifest in only 1 or 2 organ systems. The lung disease can range from severe and eventually lethal neonatal respiratory distress to chronic lung disease in childhood and adulthood. Recurrent pulmonary infections have been reported, likely caused by reduced expression of the pulmonary collectins, SP-A and SP-D, but could also result from decreased expression of other proteins. No clear genotype–phenotype correlations have emerged, but children harboring complete gene deletions have tended to have more severe and earlier-onset disease. This observation could also be related to the deletion of other adjacent genes. While limited data are available, the pulmonary phenotype may depend upon the expression of which NKX2-1 target genes are most affected. Children with decreased SP-B or ABCA3 expression may present with acute neonatal respiratory failure whereas those with decreased SP-C or pulmonary collection expression are more likely to have chronic lung disease.

Genetics

The gene is small, spanning <3,000 bases, with only 3 exons. TTF-1 is expressed not only in the lung but also in the thyroid gland, as well as in the central nervous system. In the lung it is important for the expression of a wide variety of proteins, including the surfactant proteins, ABCA3, Clara cell secretory protein, and many others. Two transcripts that differ depending upon whether the transcriptional start site is in the 1st or 2nd exon have been recognized, although the shorter transcript is the predominant one in the lung. Most mutations are thought to result in a loss of function, with the mechanism of disease thus being haploinsufficiency, but discordant effects on different target genes have been reported. The incidence of mutations and incidence and prevalence of disease are unknown; mutations in diverse ethnic groups have been recognized. Most reported mutations and deletions have occurred de novo resulting in sporadic disease, but familial disease transmitted in a dominant manner has been recognized.

Diagnosis

Sequence analysis of the *NKX2-1* gene is available through clinical laboratories and is the preferred method for diagnosis. As deletions comprise a significant fraction of reported mutant alleles, specific methods to look for such deletions should also be performed, such as a comparative genomic hybridization assay or multiplex ligation-dependent probe amplification assay. A mutation on 1 allele is sufficient to cause disease. While isolated pulmonary disease has been recognized, the majority of reported affected individuals have had manifestations in 1 or more other organ systems. Thus the presence of hypothyroidism or neurologic abnormality in a proband or a family history of chorea should prompt consideration of the diagnosis. The most specific neurologic finding is chorea, but hypotonia, developmental delay, ataxia, and dysarthria have been reported. In very young, nonambulatory infants the neurologic symptoms may not be evident, or muscle weakness or hypotonia may be attributed to the severity of lung disease or a result of the hypothyroidism. Affected individuals may not be overtly hypothyroid but have compensated hypothyroidism with borderline low T4 (thyroxine) and high thyroid-stimulating hormone levels. The lung pathology associated with *NKX2-1* mutations may be typical of that of other surfactant dysfunction disorders, but because *NKX2-1* is important for lung development, growth abnormalities and arrested pulmonary development also may be seen. Immunostaining studies of surfactant protein expression have yielded variable results, with decreased expression of 1 or more surfactant-related proteins observed in some patients. No characteristic electron microscopy findings have been identified.

TREATMENT OF SURFACTANT DYSFUNCTION DISORDERS

Virtually all patients with SP-B deficiency die within the 1st yr of life. Conventional neonatal intensive care interventions can maintain extrapulmonary organ function for a limited time (weeks to months).

Replacement therapy with commercially available surfactants is ineffective. Lung transplantation has been successful, but the pretransplantation, transplantation, and posttransplantation medical and surgical care is highly specialized and available only at pediatric pulmonary transplantation centers; prompt recognition is critical if patients are to be considered for lung transplantation. Palliative care consultation is helpful.

No specific treatment is available for patients with lung disease caused by mutations in *SFTPC* or *ABCA3*. Therapeutic approaches used for interstitial lung diseases, such as the use of corticosteroids, quinolones, and macrolide antibiotics have been reported but not systematically evaluated. Infants with severe and progressive respiratory failure attributable to ABCA3 deficiency may be candidates for lung transplantation. The variable natural history of patients with *SFTPC* mutations and older children with ABCA3 deficiency makes predictions of prognosis difficult. Lung transplantation is reserved for patients with progressive and refractory respiratory failure who would otherwise qualify for transplantation irrespective of their diagnosis.

Treatment for patients with *NKX2-1* mutations is largely supportive. Hypothyroidism if present should be treated with thyroid replacement. Corticosteroids and other agents used for other types of surfactant dysfunction have not been formally evaluated. Some individuals have progressive lung disease, and lung transplantation has been performed for some subjects with end-stage lung disease. The variable progression of disease and presence of extrapulmonary disease may make evaluation and selection of subjects for transplantation particularly difficult.

Parents of children with surfactant dysfunction disorders should be offered genetic counseling. This allows for defining the recurrence risks for future pregnancies and the availability of antenatal diagnosis and therapeutic options, as well whether testing should be offered to other family members who may not be symptomatic.

Bibliography is available at Expert Consult.

405.2 Pulmonary Alveolar Proteinosis

Lawrence M. Nogee, F. Sessions Cole III, and Aaron Hamvas

Pulmonary alveolar proteinosis (PAP) is a rare type of diffuse lung disease characterized by the intraalveolar accumulation of pulmonary surfactant. Histopathologic examination shows distal air spaces to be filled with a granular, eosinophilic material that stains positively with periodic acid–Schiff reagent and is diastase resistant. This material contains large amounts of surfactant proteins and lipids and the primary mechanism for its accumulation is impaired catabolism by alveolar macrophages. PAP has historically been classified as either primary (idiopathic) or secondary to a number of different conditions, although this terminology is evolving as specific etiologies for PAP are identified. (A fulminant, usually lethal form manifesting shortly after birth has been termed "congenital alveolar proteinosis," but because this condition is caused by disrupted surfactant metabolism or surfactant dysfunction within alveolar type II cells, the disease is included under "Inherited Disorders of Surfactant Metabolism," above (see Chapter 405.1).

ETIOLOGY AND PATHOPHYSIOLOGY

Disordered signaling of granulocyte-macrophage colony-stimulating factor (GM-CSF) leading to impaired alveolar macrophage maturation is the major underlying cause of primary PAP in children and adults. Most cases of primary PAP in older children and adults are mediated by neutralizing autoantibodies directed against GM-CSF, which can be detected in serum and bronchoalveolar lavage (BAL) fluid. These autoantibodies block binding of GM-CSF to its receptor, thereby inhibiting alveolar macrophage maturation and function and surfactant clearance. Mutations in the genes encoding both the α and β subunits of the GM-CSF receptor *(CSF2RA, CSFR2B)* in children with primary alveolar proteinosis account for a genetic basis for some cases of primary PAP in childhood. Alveolar proteinosis has also been reported in children, including young infants, with **lysinuric protein intolerance**, a rare autosomal recessive disorder caused by mutations in the cationic amino acid transporter SLC7A7 (see Chapter 85.14). These children generally present with vomiting, hyperammonemia, and failure to thrive, although their pulmonary disease may prove fatal. Defective macrophage function has been demonstrated in lysinuric protein intolerance and a case of recurrence of the disease after lung transplantation also supports a primary role for alveolar macrophage dysfunction in the pathogenesis of PAP associated with lysinuric protein intolerance. PAP is also associated with some subtypes of **Niemann-Pick disease** (see Chapter 86.4).

Secondary alveolar proteinosis also may occur in association with infection, particularly in immunocompromised individuals. However, because the same pathologic process occurs in severely immunodeficient mice raised in a pathogen-free environment, it is not clear whether this phenotype results from a secondary infection or the underlying immunodeficiency. Environmental exposures to dust, silica, and chemicals and chemotherapeutic agents have also been associated with the development of secondary alveolar proteinosis.

CLINICAL MANIFESTATIONS

Infants and children with PAP present with dyspnea, fatigue, cough, weight loss, chest pain, or hemoptysis. In the later stages, cyanosis and digital clubbing may be seen. Pulmonary function changes include decreased diffusing capacity of carbon monoxide, lung volumes with a restrictive abnormality, and arterial blood gas values indicating marked hypoxemia and/or chronic respiratory acidosis. Alveolar proteinosis in infants and children is rare. Boys are affected 3 times as often as girls. Usually there is no identifiable etiologic factor (primary), although PAP may occur in association with malignancy or infection, particularly in the setting of systemic immunosuppression or congenital immunodeficiency, or following exposure to several inciting agents, such as dust and chemicals (secondary).

DIAGNOSIS

Histopathologic examination of lung biopsy specimens currently remains the gold standard for diagnosis of PAP in children, although this is likely to change as molecular tests become available. Immunohistochemical staining reveals abundant quantities of alveolar and intracellular surfactant proteins A, B, and D. Latex agglutination tests for the presence of anti–GM-CSF antibodies in BAL fluid or blood are highly sensitive and specific for the autoimmune forms of alveolar proteinosis. Elevations of GM-CSF in peripheral blood suggest a GM-CSF receptor defect, and molecular analysis of these genes should be pursued. The examination of sputum or BAL fluid for surfactant components has been used diagnostically in adults, but these methods have not been validated in children. Examination of peripheral blood and/or bone marrow for clonogenic stimulation of monocyte-macrophage precursors, GM-CSF receptor and ligand expression, and GM-CSF binding and signaling studies are available through research protocols.

TREATMENT

The natural history of primary PAP is highly variable, making prognostic and therapeutic decisions difficult. Total lung lavage has been associated with prolonged remissions of PAP in adults and remains a therapeutic option for patients with childhood PAP (Figs. 405-1 and 405-2). Younger infants with PAP may be more likely to have genetic mechanisms underlying their disease, and the role of repeated BAL in children has not been well studied, nor is it likely to be effective. It may provide a temporizing measure in some circumstances and may benefit patients with autoimmune or secondary PAP. Subcutaneous or inhaled administration of recombinant GM-CSF may improve pulmonary function in some adults with later-onset PAP. The role of exogenous GM-CSF treatment in children has not been well studied, although successful treatment has been reported in an adolescent with autoimmune-mediated PAP. Because children with GM-CSF receptor

defects generally have high serum levels of GM-CSF, exogenous GM-CSF seems unlikely to be effective in most such cases. Depending upon the nature of the mutation(s) responsible for the deficiency, some responsiveness of the receptor may be retained such that a response to exogenous GM-CSF is possible. As the primary defect for PAP resides in the alveolar macrophage, which is a bone marrow–derived cell, lung transplantation would not be expected to correct primary PAP.

Chapter 406

Pulmonary Hemosiderosis

Mary A. Nevin

Pulmonary hemorrhage may be characterized as focal or diffuse based on the site(s) of bleeding. A detailed review of pulmonary hemorrhage is in Chapter 407.2. The diagnosis of pulmonary hemosiderosis refers to the subset of patients with **diffuse alveolar hemorrhage (DAH)**. Bleeding in DAH occurs as a result of injury to the microvasculature of the lung and may be slow and insidious due to the low pressure pulmonary circulation. Pulmonary hemosiderosis has classically been characterized by the triad of iron-deficiency anemia, hemoptysis, and multiple alveolar infiltrates on chest radiographs. However, many of those affected, particularly young patients are likely to present atypically and a high index of suspicion for this condition must be maintained. Pulmonary hemosiderosis can exist in isolation, but more commonly occurs in association with an underlying condition. A precise etiology for hemorrhage may not always be found. A diagnosis of **idiopathic pulmonary hemosiderosis (IPH)** is made when DAH occurs in isolation and an exhaustive evaluation for an underlying pathologic etiology is found to be unrevealing.

ETIOLOGY

Current classification schemes organize the etiologies of pulmonary hemosiderosis on the basis of the presence of absence of pulmonary capillaritis; a pathologic process that is characterized by inflammation and cellular disruption of the alveolar interstitium and capillary bed. Although the finding of pulmonary capillaritis is nonspecific with regard to underlying diagnosis, its presence appears to be an important negative prognostic factor in DAH and may indicate an underlying systemic vasculitic process or collagen vascular disease.

Disorders associated with pulmonary capillaritis may include systemic lupus erythematosus (SLE; see Chapter 158), drug-induced capillaritis, granulomatosis with polyangiitis (previously Wegener granulomatosis), Goodpasture syndrome, and Henoch-Schönlein purpura (see Chapter 167). The finding of DAH in patients with granulomatosis with polyangiitis and microscopic polyangiitis (MPA) (see Chapter 167) is frequently associated with pathologic evidence of pulmonary capillaritis. In patients with Goodpasture syndrome or SLE, DAH has been reported both with and without the associated finding of capillaritis. A number of systemic autoimmune and inflammatory disorders may predispose a host to DAH with pulmonary capillaritis. Similarly, a variety of drugs are associated with pulmonary capillaritis but the mechanisms here have not been identified.

These disorders are distinguished from those without pulmonary capillaritis. Those disorders in which the pathologic finding of capillary

Table 406-1 Diffuse Alveolar Hemorrhage Syndromes

CLASSIFICATION	SYNDROME
Disorders with pulmonary capillaritis	Idiopathic pulmonary capillaritis
	Granulomatosis with polyangiitis (Wegener granulomatosis)
	Microscopic polyangiitis
	Systemic lupus erythematosus
	Goodpasture syndrome
	Antiphospholipid antibody syndrome
	Henoch-Schönlein purpura
	Immunoglobulin A nephropathy
	Behçet syndrome
	Cryoglobulinemia
	Drug-induced capillaritis (hypersensitivity)
	Idiopathic pulmonary-renal syndrome
	Eosinophilic granulomatosis angiitis (Churg-Strauss syndrome)
Disorders without pulmonary capillaritis:	
Noncardiovascular causes	Idiopathic pulmonary hemosiderosis
	Heiner syndrome
	Acute idiopathic pulmonary hemorrhage of infancy
	Bone marrow transplantation
	Immunodeficiency
	Coagulation disorders
	Hemolytic uremic syndromes
	Celiac disease (Lane-Hamilton syndrome)
	Infanticide (child abuse)
	Infection (HIV, cryptococcosis, Legionnaires disease)
Cardiovascular causes	Mitral stenosis
	Pulmonary venoocclusive disease
	Arteriovenous malformations
	Pulmonary lymphangioleiomyomatosis
	Pulmonary hypertension
	Pulmonary capillary hemangiomatosis
	Chronic heart failure
	Vascular thrombosis with infarction

From Susarla SC, Fan LL: Diffuse alveolar hemorrhage syndromes in children, Curr Opin Pediatr 19:314–320, 2007.

network disruption is absent are further divided into cardiac (pulmonary hypertension, mitral stenosis) and noncardiac (immunodeficiency, Heiner syndrome, coagulopathies, IPH) etiologies. A summary of the diagnoses that may manifest as recurrent or chronic pulmonary bleeding; Table 406-1 lists their classification.

EPIDEMIOLOGY

Disorders that present as DAH are highly variable in their severity, as well as in their associated symptomatology and identifiable abnormalities in laboratory testing; the diagnosis may be significantly delayed, making frequency estimates unreliable. Similarly, the prevalence of IPH is largely unknown. Among many children and young adults who were diagnosed with IPH in the past, the etiology of the hemorrhage might have been discovered if they had been studied with the newer and more advanced diagnostics available today; specific serologic testing has vastly improved our ability to appreciate immune mediated disease. Estimates of prevalence obtained from Swedish and Japanese retrospective case analyses vary from 0.24-1.23 cases per million. In nearly 80% of diagnosed cases the manifestations of IPH are seen before age 10 yr. The remaining 20% of cases are typically diagnosed before age 30 yr. The ratio of affected males : females is 1 : 1 in the childhood diagnosis group, and men are only slightly more affected in the group diagnosed as young adults.

PATHOLOGY

In pulmonary capillaritis, key histologic features include (1) fibrin thrombi, which occlude capillaries, (2) fibrin clots adherent to interalveolar septae, (3) fibrinoid necrosis of capillary walls, and (4) interstitial erythrocytes and **hemosiderin**. Illustrative but nonspecific pathologic findings, such as vascular smooth muscle hypertrophy (pulmonary hypertension), edema (mitral stenosis), or thrombosis (vascular thrombosis with infarction), may be found in those disorders that cause DAH without pulmonary capillaritis. The finding of blood in the airways or alveoli is representative of a recent hemorrhage. With repeated episodes of pulmonary hemorrhage, lung tissue appears brown secondary to this presence of hemosiderin. **Hemosiderin-laden macrophages (HLMs)** are seen with recovering, recurrent, or chronic pulmonary hemorrhage and are identifiable both in bronchoalveolar lavage fluid and in pathologic specimens of lung tissue. It takes 48-72 hr for the alveolar macrophages to convert iron from erythrocytes into hemosiderin. In a murine model, HLMs appear 3 days after a single episode of pulmonary hemorrhage and peak at 7-10 days. HLMs may be detectable for weeks to months after a hemorrhagic event. Other nonspecific pathologic findings include thickening of alveolar septa, goblet cell hyperplasia, and hypertrophy of type II pneumocytes. Fibrosis may be seen with chronic disease.

PATHOPHYSIOLOGY

Diffuse Alveolar Hemorrhage Associated with Pulmonary Capillaritis

Granulomatosis with polyangiitis is a recognized etiology for DAH in children. This disease is classically characterized by necrotizing granuloma formation (with or without cavitation) of the upper and lower respiratory tract and by a necrotizing glomerulonephritis and small vessel vasculitis. In children, presentations attributable to the upper airway, including subglottic stenosis, may suggest the diagnosis. The presence of **antineutrophil cytoplasmic antibodies (ANCAs)** may be helpful in diagnosis and management, but the clinician must be aware that other ANCA-positive vasculitides, such as MPA and Churg-Strauss syndrome, may share this nonspecific laboratory finding. In small-vessel vasculitides, ANCAs cause an inflammatory reaction that results in injury to the microvasculature. **Antiproteinase-3 antibodies** (**cANCA**) are classically associated with granulomatosis with polyangiitis whereas **antimyeloperoxidase antibodies** (**pANCA**) are typically found in patients with MPA.

Patients with **MPA** (previously the microscopic variant of polyarteritis nodosa) demonstrate a systemic necrotizing vasculitis with a predilection for small vessels (venules, arterioles, capillaries) but without necrotizing granuloma formation. This diagnosis is precluded by the finding of immune complex deposition in order to differentiate MPA from other diseases (Henoch-Schönlein purpura, cryoglobulinemic vasculitis) that are associated with immune complex–mediated small-vessel vasculitis.

Goodpasture syndrome is an immune complex–mediated disease in which anti–glomerular basement membrane (GBM) antibody binds to the basement membrane of both the alveolus and the glomerulus. GBM antibodies attach to type IV collagen contained in the vascular endothelium. At the alveolar level, immunoglobulin (Ig) G, IgM, and complement are deposited at alveolar septa. Electron microscopy shows disruption of basement membranes and vascular integrity, which allows blood to escape into alveolar spaces.

Although alveolar hemorrhage is not commonly encountered in association with SLE, its occurrence is often severe and potentially life-threatening; mortality rates exceed 50%. Pathologic vasculitic features may be absent. Some immunofluorescent studies have revealed IgG and C3 deposits at the alveolar septa. However, a clear link between immune complex formation and alveolar hemorrhage has not been established.

In **Henoch-Schönlein purpura,** pulmonary hemorrhage is a rare but recognized complication. Pathologic findings have included transmural neutrophilic infiltration of small vessels, alveolar septal inflammation, and intra-alveolar hemorrhage. Vasculitis is the proposed mechanism for hemorrhage.

Pulmonary renal syndromes are defined as those where pulmonary and renal disease manifestations are predominant. These include the aforementioned granulomatosis with polyangiitis, Goodpasture

syndrome, SLE, and MPA. As Henoch-Schönlein purpura may also have renal involvement, it has been suggested for inclusion as a pulmonary renal syndrome.

Diffuse Alveolar Hemorrhage Not Associated with Pulmonary Capillaritis

A premature infant's neonatal course can be complicated by pulmonary hemorrhage. The alveolar and vascular networks are immature and particularly prone to inflammation and damage by ventilator mechanics, oxidative stress, and infection. Pulmonary hemorrhage may be unrecognized if the volume of blood is insufficient to reach the proximal airways. The chest radiographic findings in pulmonary hemorrhage may be appreciated instead as a worsening picture of respiratory distress syndrome, edema, or infection.

Pulmonary hemosiderosis in association with **cow's milk hypersensitivity** was first reported by Heiner in 1962. This condition is characterized by variable symptoms of milk intolerance. Symptoms can include grossly bloody or occult heme-positive stools, vomiting, failure to thrive, symptoms of gastroesophageal reflux, and/or upper airway congestion. Pathologic findings have included elevations of IgE and peripheral eosinophilia, as well as alveolar deposits of IgG, IgA, and C3. High titers to cow's milk protein are also typically found in cow's milk hypersensitivity. Association with pulmonary hemorrhage has remained controversial but multiple case series have provided support for the anecdotal association. In one series, infants presenting with recurrent respiratory symptoms and iron-deficiency anemia; all infants improved with elimination of cow's milk from their diets and a subset thereafter had a recurrence of pulmonary disease with a cow's milk challenge. However, many patients with milk precipitins did not have symptoms of hemosiderosis and patients with hemosiderosis did not always have milk precipitins; the relationship may be an association rather than causal in nature.

A number of case reports and case series have suggested an association between **celiac disease** (see Chapter 338.2) and DAH. In these reports, a resolution of intestinal and pulmonary symptoms along with resolution of radiographic disease has been seen after the adoption of a gluten-free diet. Consideration of testing for celiac disease in those patients with pulmonary hemorrhage and suggestive gastrointestinal symptomatology is suggested.

A number of additional associated conditions and exposures exist as causes for DAH. These are typically noninflammatory in nature and may be diversely attributable to cardiac, vascular, lymphatic or hematologic etiologies. **Graft-versus-host disease** has been implicated in transplant recipients and DAH may rarely be attributable to nonaccidental trauma. These etiologies for DAH occur relatively infrequently in the pediatric population, and suggested mechanisms for hemorrhage are variable.

The diagnosis of IPH is a diagnosis of exclusion and is only made when there is evidence of chronic or recurrent DAH and when exhaustive evaluations for primary or secondary etiologies have negative results. Renal and systemic involvement should be absent and a biopsy specimen should not reveal any evidence of granulomatous disease, vasculitis, infection, infarction, immune complex deposition or malignancy. Some patients initially diagnosed with IPH will later be found to have Goodpasture syndrome, SLE, or MPA; therefore, some cases of IPH may represent unrecognized immune-mediated disorders.

CLINICAL MANIFESTATIONS

The clinical presentation of pulmonary hemosiderosis is highly variable. In most symptomatic cases, DAH is heralded by symptoms of hemoptysis and dyspnea with associated hypoxemia and the finding of alveolar infiltration on chest radiograph. The diagnosis may be problematic as young children often lack the ability to effectively expectorate and may not present with hemoptysis. As the presence of blood in the lung is a trigger for airway irritation and inflammation, the patient may present after an episode of hemorrhage with wheezing, cough, dyspnea, and alterations in gas exchange, reflecting bronchospasm, edema, mucus plugging, and inflammation; this presentation may result in an incorrect diagnosis of asthma or bronchiolitis. A lack of pulmonary symptoms does not preclude the diagnosis of DAH and children may present only with chronic fatigue or pallor.

Symptoms may reflect an underlying and associated disease process rather than specifically related to pulmonary hemorrhage. Presentations can vary widely from a relative lack of symptoms to shock or sudden death. Bleeding may occasionally be recognized from the presence of alveolar infiltrates on a chest radiograph alone. It should be noted, however, that the absence of an infiltrate does not rule out an ongoing hemorrhagic process.

On physical examination, the patient may be pale with tachycardia and tachypnea. During an acute exacerbation, children are frequently febrile. Examination of the chest may reveal retractions and differential or decreased aeration, with crackles or wheezes. The patient may present in shock with respiratory failure from massive hemoptysis. Children in particular may present with symptoms of chronic anemia, such as failure to thrive.

LABORATORY FINDINGS AND DIAGNOSIS

Pulmonary hemorrhage is classically associated with a microcytic, hypochromic anemia. Reductions of serum iron levels, decreased or normal total iron-binding capacity and normal to increased ferritin levels may be found with chronic disease. An elevated erythrocyte sedimentation rate is a nonspecific finding. The reticulocyte count is frequently elevated. Patients with pulmonary capillaritis have lower hematocrits and higher erythrocyte sedimentation rates. The anemia of IPH can mimic a hemolytic anemia. Elevations of plasma bilirubin are caused by absorption and breakdown of hemoglobin in the alveoli. Any or all of these hematologic manifestations may be absent in the presence of recent hemorrhage.

White blood cell count and differential should be evaluated for evidence of infection and eosinophilia. A peripheral smear and direct Coombs test may suggest a vasculitic process. A stool specimen positive for occult blood may suggest associated gastrointestinal disease but can also reflect swallowed blood. Renal and liver functions should be reviewed. A urinalysis should be obtained to assess for evidence of a pulmonary–renal syndrome. A coagulation profile, quantitative immunoglobulins (including IgE), and complement studies are recommended. Testing for von Willebrand disease is also indicated.

Testing for ANCA (cANCA, pANCA), antinuclear antibody, double-stranded DNA, rheumatoid factor, antiphospholipid antibody, and GBM antibody evaluates for a number of immune-mediated and vasculitic processes that may be associated with pulmonary capillaritis.

Sputum or pulmonary secretions should be analyzed for significant evidence of blood or HLMs and may provide supportive evidence in a patient who is able to adequately expectorate secretions from the lower airway. Gastric secretions may also reveal HLMs. Flexible bronchoscopy provides visualization of any areas of active bleeding. With bronchoalveolar lavage, pulmonary secretions may be sent for pathologic review and culture analysis. The ability to perform flexible bronchoscopy will be limited if there are large amounts of blood or clots in the airway. Active bleeding may be exacerbated by airway occlusion with a bronchoscope and by installation of fluid. A patient with respiratory failure can be ventilated more effectively through a rigid bronchoscope.

Chest x-rays may reveal evidence of acute or chronic disease. Hyperaeration is frequently seen, especially during an acute hemorrhage. Infiltrates are typically symmetric and may spare the apices of the lung. Atelectasis may also be appreciated. With chronic disease, fibrosis, lymphadenopathy and nodularity may be seen. CT findings may demonstrate a subclinical and contributory disease process. The presence of a cardiac murmur, cardiomegaly on X-ray or a clinical suspicion for left-sided heart lesion suggests the need for a complete cardiac evaluation, including electrocardiogram and echocardiogram

Pulmonary function testing will likely reveal primarily obstructive disease in the acute period. With more chronic disease, fibrosis and restrictive disease tend to predominate. Oxygen saturation levels may be decreased. Lung volumes may reveal air trapping acutely and decreases in total lung capacity chronically. The diffusing capacity of carbon monoxide may be low or normal in the chronic phase

but is likely to be elevated in the setting of an acute hemorrhage, because carbon monoxide binds to the hemoglobin in extravasated red blood cells.

Lung biopsy is warranted when DAH occurs without discernible etiology, extrapulmonary disease, or circulating GBM antibodies. When obtained, pulmonary tissue should be evaluated for evidence of vasculitis, immune complex deposition, and granulomatous disease.

Many have supported a diagnosis of IPH without lung biopsy if the patient has a typical presentation with diffuse infiltration on radiography, anemia, HLMs in bronchoalveolar lavage, sputum or gastric aspirate, absence of systemic disease and negative serology for immune-mediated disease. However, a number of patients meeting these criteria have been proven to have pulmonary capillaritis on review of pathologic lung tissue specimens. Therefore, a lung biopsy is recommended in any child presenting with DAH of uncertain etiology.

TREATMENT

Supportive therapy, including volume resuscitation, ventilatory support, supplemental oxygen, and transfusion of blood products, may be warranted in the patient with pulmonary hemosiderosis. Surgical or medical therapy should be directed at any treatable underlying condition. In IPH, systemic corticosteroids are frequently utilized as first-line treatment and are expected to be of particular benefit in the setting of immune-mediated disease. Steroids modulate neutrophil influx and the inflammation associated with hemorrhage; consequently, they may decrease progression toward fibrotic disease.

Treatment may be provided in the form of methylprednisolone 2-4 mg/kg/day divided every 6 hr or in the form of prednisone 0.5-1 mg/kg daily and decreased to every-other-day after resolution of acute symptoms. Successful treatment is also associated with the use of pulse steroid therapy; methylprednisolone may be given at a dose of 10-30 mg/kg (maximum 1 g) infused over 1 hr for 3 consecutive days and repeated monthly. Early treatment with corticosteroids appears to decrease episodes of hemorrhage. Steroid therapy is associated with improved survival and may be tapered as tolerated with disease remission or chronically maintained.

Steroid-sparing agents, including cyclophosphamide, azathioprine, hydroxychloroquine, methotrexate, and intravenous immunoglobulin, have been successfully used as adjunctive therapy in patients with chronic, unremitting or recurrent hemorrhage. Maintenance therapy with 6-mercaptopurine may produce favorable results in achieving long-term remission. The potential adverse effects of these pharmacologic interventions should be recognized and treated patients must be closely monitored for drug-related complications. Cushing syndrome is a well-recognized complication of chronic steroid therapy. Thrombocytopenia in association with low-dose cyclophosphamide has also been reported. Chronically immunosuppressed patients are at risk for opportunistic infection; *Legionella* pneumonia infection has been described in a survivor of IPH.

Plasmapheresis is a recognized therapy for anti-GBM antibody disease. Intravenous immunoglobulin has been used in immune complex–mediated disease.

In chronic disease, progression to debilitating pulmonary fibrosis has been described. Lung transplantation has been performed in patients with IPH refractory to immunosuppressive therapy. In one reported case study, IPH recurred in the transplanted lung.

PROGNOSIS

The outcome of patients suffering from DAH is largely dependent on the underlying disease process. Some conditions respond well to immunosuppressive therapies and remissions of disease are well documented. Other syndromes, especially those associated with pulmonary capillaritis, carry a poorer prognosis. In IPH, mortality is usually attributable to massive hemorrhage or, alternatively, to progressive fibrosis, respiratory insufficiency, and right-sided heart failure.

Long-term prognosis in patients with IPH varies among studies. Initial case study reviews suggested an average survival after symptom onset of only 2.5 yr. In this early review, a minority of patients were treated with steroids. Recent reviews have demonstrated vastly improved 5yr (86%) and 8 yr (93%) survival in association with the use of immunosuppressive therapies. To date, specific immunosuppressive treatment regimens have not been studied in a prospective manner.

Chapter 407

Pulmonary Embolism, Infarction, and Hemorrhage

407.1 Pulmonary Embolus and Infarction

Mary A. Nevin

Venous thromboembolic disease (VTE) has become an increasingly recognized critical problem in children and adolescents with chronic disease, as well as in those patients without identifiable risk factors (Table 407-1). Improvements in survival with chronic illness have likely contributed to the larger number of children presenting with these thromboembolic events; they are a significant source of morbidity and mortality and may only be recognized on post mortem examination. A high level of clinical suspicion and appropriate identification of at-risk individuals is therefore recommended.

ETIOLOGY

No single classification scheme exists for the etiology of VTE. A number of risk factors may be identified in children and adolescents; the presence of immobility, malignancy, pregnancy, infection, indwelling central venous catheters and a number of inherited and acquired thrombophilic conditions have all been identified as placing an individual at risk. In children, a significantly greater percentage of VTEs are risk associated as compared with their adult counterparts. Children with **deep venous thrombosis (DVT)** and **pulmonary embolism (PE)** are much more likely to have 1 or more identifiable conditions or circumstances placing them at risk. In a retrospective cohort of patients with VTE in U.S. children's hospitals from 2001-2007, the majority (63%) of affected children were found to have 1 or more chronic medical comorbidities. In a large Canadian registry, 96% of pediatric patients were found to have 1 risk factor and 90% had 2 or more risk factors. In contrast, approximately 60% of adults with this disorder have an identifiable risk factor (see Table 407-1).

Embolic disease in children is varied in its origin. An embolus can contain thrombus, air, amniotic fluid, septic material, or metastatic neoplastic tissue. Thromboemboli are the type most commonly encountered. A commonly encountered risk factor for DVT and PE in the pediatric population is the presence of a central venous catheter. More than 50% of DVTs in children and more than 80% in newborns are found in patients with indwelling central venous lines. The presence of a catheter in a vessel lumen, as well as instilled medications, can induce endothelial damage and favor thrombus formation.

Children with malignancies are also at considerable risk. Although PE has been described in children with leukemia, the risk of PE is more significant in children with solid rather than hematologic malignancies. A child with malignancy may have numerous risk factors related to the primary disease process and the therapeutic interventions. Infection from chronic immunosuppression may interact with hypercoagulability of malignancy and chemotherapeutic effects on the endothelium.

Table 407-1	Risk Factors for Pulmonary Embolism
ENVIRONMENTAL	
Long-haul air travel	
Obesity	
Cigarette smoking	
Hypertension	
Immobility	
WOMEN'S HEALTH	
Oral contraceptives, including progesterone-only and, especially, third-generation pills	
Pregnancy	
Hormone replacement therapy	
Septic abortion	
MEDICAL ILLNESS	
Previous pulmonary embolism or deep venous thrombosis	
Cancer	
Heart failure	
Chronic obstructive pulmonary disease	
Diabetes mellitus	
Inflammatory bowel disease	
Antipsychotic drug use	
Long-term indwelling central venous catheter

Modified from Goldhaber SZ: Pulmonary embolism, Lancet *363:1295–1305, 2004.*

In a retrospective cohort of patients with VTE from 2001-2007, pediatric malignancy was the medical condition most strongly associated with recurrent VTE.

In the neonatal period, thromboembolic disease and PE may be related to indwelling catheters used for parenteral nutrition and medication delivery. **Pulmonary thromboemboli** in neonates generally occurs as a complication of underlying disease; the most common associated diagnosis is congenital heart disease but sepsis and birth asphyxia are also notable associated conditions. Other risk factors include a relative immaturity of newborn infants' coagulation; plasma concentrations of vitamin K–dependent coagulation factors (II, VII, IX, X); factors XII, XI, and prekallikrein and high-molecular-weight kininogen are only approximately half of adult levels (see Chapter 475). PE in neonates may occasionally reflect maternal risk factors, such as diabetes and toxemia of pregnancy. Infants with congenitally acquired homozygous deficiencies of antithrombin, protein C, and protein S are also more likely to present with thromboembolic disease in the neonatal period (see Chapter 478).

Pulmonary air embolism is a defined entity in the newborn or young infant and is attributed to the conventional ventilation of critically ill (and generally premature) infants with severe pulmonary disease. In the majority of instances, the pulmonary air embolism is preceded by an air-leak syndrome. Infants may become symptomatic and critically compromised by as little as 0.4 mL/kg of intravascular air; these physiologic derangements are thought to be secondary to the effects of nitrogen.

Prothrombotic disease can also manifest in older infants and children. Disease can be congenital or acquired. **Inherited thrombophilic** conditions include deficiencies of antithrombin, protein C, and protein S, as well as mutations of *factor V Leiden* (G1691A) (see Chapter 478) and *prothrombin (factor II 20210A mutation)* (see Chapter 478), and elevated values of *lipoprotein A. In addition, multiple acquired thrombophilic conditions exist; these include the presence of lupus anticoagulant (may be present without the diagnosis of systemic lupus erythematosus), anticardiolipin antibody, and anti–β_2-glycoprotein 1 antibody*. Finally, conditions such as hyperhomocysteinemia (see Chapter 86) may have both inheritable and dietary determinants. All have all been linked to thromboembolic disease. DVT/PE may be the initial presentation.

Children with sickle cell disease are also at high risk for pulmonary embolus and infarction. Acquired prothrombotic disease is seen in conditions such as *nephrotic syndrome* (see Chapter 527) and *antiphospholipid antibody syndrome.* From one-quarter to one-half of children with *systemic lupus erythematosus* (see Chapter 158) have thromboembolic disease. There is a significant association with VTE onset in children for each inherited thrombophilic trait evaluated, thereby illuminating the importance of screening for thrombophilic conditions for those at risk for VTE.

Other risk factors include infection, cardiac disease, recent surgery, and trauma. Surgical risk is thought to be more significant when immobility will be a prominent feature of the recovery. Use of oral contraceptives confers additional risk, although the level of risk in patients taking these medications appears to be decreasing, perhaps as a result of the lower amounts of estrogen in current formulations.

Septic emboli are rare in children but may be caused by osteomyelitis, jugular vein or umbilical thrombophlebitis, cellulitis, urinary tract infection, and right-sided endocarditis.

EPIDEMIOLOGY

A retrospective cohort study was performed with patients younger than 18 yr of age, discharged from 35-40 children's hospitals across the United States from 2001-2007. During this time, a dramatic increase was noted in the incidence of VTE; the annual rate of VTE increased by 70% from 34 to 58 cases per 10,000 hospital admissions. Although this increased incidence was noted in all age groups, a bimodal distribution of patient ages was found, consistent with prior studies; infants younger than 1 yr of age and adolescents made up the majority of admissions with VTE, but neonates continue to be at greatest risk. The peak incidence for VTE in childhood appears to occur in the 1st mo of life. It is in this neonatal period that thromboembolic events are more problematic, likely as a result of an imbalance between procoagulant factors and fibrinolysis. According to a 2013 update by Nowak-Göttl et al, the yearly incidence of venous events was estimated at 5.3 per 10,000 hospital admissions in children and 24 per 10,000 in the neonatal intensive care.

Pediatric autopsy reviews have estimated the incidence of thromboembolic disease in children as between 1% and 4%, although not all were clinically significant. Thromboembolic pulmonary disease is often unrecognized, and antemortem studies may underestimate the true incidence. Pediatric deaths from isolated pulmonary emboli are rare. Most thromboemboli are related to central venous catheters. The source of the emboli may be lower or upper extremity veins as well as the pelvis and right heart. In adults, the most common location for DVT

is the lower leg. However, one of the largest pediatric VTE/PE registries found two-thirds of DVTs occurring in the upper extremity.

PATHOPHYSIOLOGY

Favorable conditions for thrombus formation include injury to the vessel endothelium, hemostasis, and hypercoagulability. In the case of PE, a thrombus is dislodged from a vein, travels through the right atrium and lodges within the pulmonary arteries. In children, emboli that obstruct <50% of the pulmonary circulation are generally clinically silent unless there is significant coexistent cardiopulmonary disease. In severe disease, **right ventricular** afterload is increased with resultant right ventricular dilation and increases in right ventricular and pulmonary arterial pressures. In severe cases, a reduction of cardiac output and hypotension may result from concomitant decreases in left ventricular filling. In rare instances of death from massive pulmonary embolus, marked increases in pulmonary vascular resistance and heart failure are usually present.

Arterial hypoxemia results from unequal ventilation and perfusion; the occlusion of the involved vessel prevents perfusion of distal alveolar units, thereby creating an increase in dead space and hypoxia with an elevated alveolar–arterial oxygen tension difference (see Chapter 373). Most patients are hypocarbic secondary to hyperventilation, which often persists even when oxygenation is optimized. Abnormalities of oxygenation and ventilation are likely to be less significant in the pediatric population, possibly owing to less underlying cardiopulmonary disease and greater reserve. The vascular supply to lung tissue is abundant, and pulmonary infarction is unusual with pulmonary embolus but may result from distal arterial occlusion and alveolar hemorrhage.

CLINICAL MANIFESTATIONS

Presentation is variable, and many pulmonary emboli are silent. Rarely, a massive PE may manifest as cardiopulmonary failure. Children are more likely to have underlying disease processes or risk factors but might still present asymptomatically with small emboli. Common symptoms and signs of PE caused by larger emboli include hypoxia (cyanosis), dyspnea, cough, pleuritic chest pain, and hemoptysis. Pleuritic chest pain is the most common presenting symptom in adolescents (84%), whereas unexplained and persistent tachypnea may suggest PE in all pediatric patients. Localized crackles may occasionally be appreciated on examination. A high level of clinical suspicion is required because a variety of diagnoses may cause similar symptoms; nonspecific complaints may frequently be attributed to an underlying disease process or an unrelated/incorrect diagnosis. Confirmatory testing should follow a clinical suspicion for PE. In adults, clinical prediction rules have been published and are based on risk factors, clinical signs, and symptoms. No such clinical prediction rules have been validated in the pediatric population.

LABORATORY FINDINGS AND DIAGNOSIS

The electrocardiogram, arterial blood gas, and chest radiograph may be utilized to rule out contributing or comorbid disease but are not sensitive or specific in the diagnosis of PE. Electrocardiographs may reveal ST-segment changes or evidence of pulmonary hypertension with right ventricular failure (cor pulmonale); such changes are nonspecific and nondiagnostic. Radiographic images of the chest are often normal in a child with PE and any abnormalities are likely to be nonspecific. Patients with septic emboli may have multiple areas of nodularity and cavitation, which are typically located peripherally in both lung fields. Many patients with PE have hypoxemia. The alveolar–arterial oxygen tension difference gradient is more sensitive in detecting gas exchange derangements.

A review of results of a complete blood count, urinalysis, and coagulation profile is warranted. Prothrombotic diseases should be highly suspected on the basis of past medical or family history; additional laboratory evaluations include fibrinogen assays, protein C, protein S, and antithrombin III studies, and analysis for factor V Leiden mutation, as well as evaluation for lupus anticoagulant and anticardiolipin antibodies.

Echocardiograms may be warranted to assess ventricular size and function. An echocardiogram is required if there is any suspicion of intracardiac thrombi or endocarditis.

Noninvasive venous ultrasound testing with Doppler flow can be used to confirm DVT in the lower extremities; ultrasonography may not detect thrombi in the upper extremities or pelvis (Fig. 407-1*A*). In patients with significant venous thrombosis, D dimers are usually elevated. It is a sensitive but nonspecific test for venous thrombosis. The D dimer may not be clinically relevant in the children with PE as this group is more likely to have an underlying comorbid condition that is also associated with an increased level of D dimers. When a high level of suspicion exists, confirmatory testing with venography should be pursued. DVT can be recurrent and multifocal and may lead to repeated episodes of PE.

Although a ventilation–perfusion ($\dot{V}$-$\dot{Q}$) radionuclide scan is a noninvasive and potentially sensitive method of pulmonary embolus detection, the interpretation of $\dot{V}$-$\dot{Q}$ scans can be problematic. Helical or spiral CT with an intravenous contrast agent is valuable and the diagnostic test of choice to detect a PE (see Fig. 407-1*B*). CT studies detect emboli in lobar and segmental vessels with acceptable sensitivities. Poorer sensitivities may be encountered in the evaluation of the subsegmental pulmonary vasculature. Pulmonary angiography is the

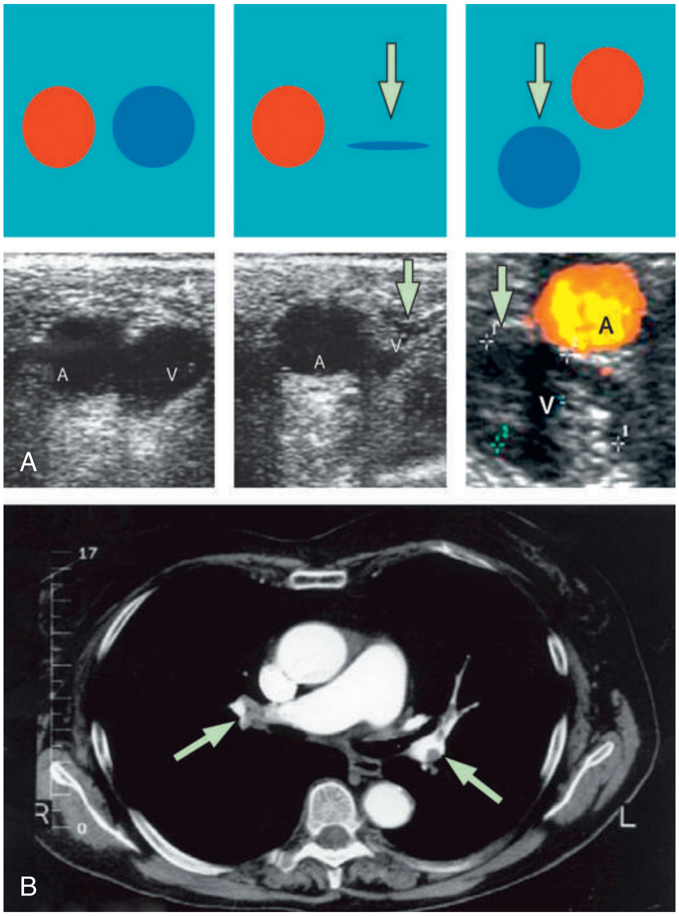

Figure 407-1 A, Compression ultrasound. Upper series, from left to right, representation of vein and artery without and with *(arrow)* gentle compression with the echocardiographic probe; lower series, corresponding echocardiographic findings. The third image from the left show a thrombus in the vein (vein not compressible by the probe). **B,** CT angiography. CT angiography showing several emboli (arrows) in the main right pulmonary artery and in left lobar and segmental arteries. A, artery; V, vein. *(From Goldhaber SZ, Bounameaux H: Pulmonary embolism and deep vein thrombosis.* Lancet *379:1835–1844, 2012, Fig. 2, p. 1838.)*

gold standard for diagnosis of PE, but with current availability of multidetector spiral CT angiography, it is not necessary except in unusual cases.

MRI may be emerging as a diagnostic option for patients with VTE. The accuracy of this method is similar to that of multidetector CT. It may be preferable in patients with allergic reactions to contrast material and in pediatric patients in whom the risk of early exposure to ionizing radiation has been established.

TREATMENT

Initial treatment should always be directed toward stabilization of the patient. Careful approaches to ventilation, fluid resuscitation, and inotropic support are always indicated, because improvement in 1 area of decompensation can often exacerbate coexisting pathology.

After the patient with a PE has been stabilized, the next therapeutic step is anticoagulation. Evaluations for prothrombotic disease must precede anticoagulation. Acute-phase anticoagulation therapy may be provided with **unfractionated heparin (UFH)** or **low-molecular-weight heparin (LMWH)**. Heparins act by enhancing the activity of antithrombin. LMWH is generally preferred in children; this drug can be administered subcutaneously and the need for serum monitoring is decreased. The risk of **heparin-induced thrombocytopenia** is also decreased with LMWH as compared to UFH. Alternatively, UFH is preferred with patients who have an elevated risk of bleeding as UFH has a shorter half-life than LMWH. UFH is also used preferentially in patients with compromised renal function. In monitoring of drug levels, laboratories must be aware of the drug chosen in order to use the appropriate assay. For UFH, the therapeutic range is 0.3-0.7 anti-Xa activity units/mL. In LMWH, the therapeutic range is 0.5-1.0 units/mL. When the anti-Xa assay is not available, the activated **partial thromboplastin time** may be used with a goal of 60-85 sec or approximately 1.5-2 times the upper limit of age appropriate normal values. The recommended duration of heparinization during acute treatment is 5-10 days; this length of therapy has been extrapolated from adult data. Long-term therapy with heparin should be avoided whenever possible. Side effects include the aforementioned heparin-induced thrombocytopenia as well as bleeding and osteoporosis.

Extension of anticoagulation therapy occurs in the subacute phase and may utilize LMWH or warfarin. Warfarin is generally initiated after establishing effective anticoagulation with heparin because severe congenital deficiencies of protein C may be associated with warfarin skin necrosis. The starting dose for warfarin in children is generally 0.1 mg/kg orally administered once daily. Monitoring is via the international normalized ratio (INR) and the therapeutic INR range for warfarin therapy in VTE is 2.0-3.0. The INR is generally monitored 5 days after initiating therapy or a similar period after dose changes and weekly thereafter until stable. The INR should be obtained with any evidence of abnormal bleeding and should be discontinued at least 5 days prior to invasive procedures. The utilization of an anticoagulation team and/or established treatment algorithms is recommended in order to optimize patient safety. With a first occurrence of VTE, anticoagulation is recommended for 3-6 mo in the setting of an identifiable, reversible, and resolved risk factor (e.g., postoperative state). Longer treatment is indicated in patients with idiopathic VTE (6-12 mo) and in those with chronic clinical risk factors (12 mo-lifelong). In the setting of a congenital thrombophilic condition, the duration of therapy is often indefinite.

Inhibitors of factor Xa (rivaroxaban, etc.) may become an alternate therapy for both acute PE and long-term treatment.

Thrombolytic agents such as recombinant tissue plasminogen activator, may be utilized in combination with anticoagulants in the early stages of treatment; their use is most likely to be considered in children with hemodynamically significant PE (echocardiogram evidence of right ventricular dysfunction) or other severe potential clinical sequelae of VTE. Combined therapy may reduce the incidences of progressive thromboembolism, pulmonary embolus, and post-thrombotic syndrome. Mortality rate appears to be unaffected by additional therapies; nonetheless, the additional theoretic risk of hemorrhage limits the use of combination therapy in all but the most compromised patients. The use of thrombolytic agents in patients with active bleeding, recent cerebrovascular accidents, or trauma is contraindicated.

Surgical embolectomy is invasive and is associated with significant mortality. Its application should be limited to those with persistent hemodynamic compromise refractory to standard therapy.

PROGNOSIS

Mortality in pediatric patients with PE is likely to be attributable to an underlying disease process rather than to the embolus itself. Short-term complications include major hemorrhage (either due to the thrombosis or secondary to anticoagulation). Conditions associated with a poorer prognosis include malignancy, infection, and cardiac disease. The mortality rate in children from PE is 2.2%. Recurrent thromboembolic disease may complicate recovery. The practitioner must conduct an extensive evaluation for underlying pathology so as to prevent progressive disease. Postthrombotic syndrome is another recognized complication of pediatric thrombotic disease. Venous valvular damage can be initiated by the presence of DVT, leading to persistent venous hypertension with ambulation and valvular reflux. Symptoms include edema, pain, increases in pigmentation, and ulcerations. Affected pediatric patients may suffer lifelong disability.

407.2 Pulmonary Hemorrhage and Hemoptysis

Mary A. Nevin

Pulmonary hemorrhage is relatively uncommon but a potentially fatal occurrence in children. The patient with suspected hemoptysis may present acutely or subacutely and to a variety of different practitioners with distinct areas of specialty. Diffuse, slow bleeding in the lower airways may become severe and manifest as anemia, fatigue, or respiratory compromise without the patient ever experiencing episodes of hemoptysis. Hemoptysis must also be separated from episodes of hematemesis or epistaxis, each of which may have indistinguishable presentations in the young patient.

ETIOLOGY

Tables 407-2 and 406-1 (in Chapter 406) present conditions that can manifest as pulmonary hemorrhage or hemoptysis in children. The chronic (opposed to an acute) presence of a foreign body can lead to inflammation and/or infection, thereby inducing hemorrhage. Bleeding is more likely to occur in association with a chronically retained foreign body of vegetable origin.

Hemorrhage most commonly reflects chronic inflammation and infection such as that seen with bronchiectasis due to cystic fibrosis or with cavitary disease in association with infectious tuberculosis. Hemoptysis may occasionally reflect an acute and intense infectious condition such as bronchitis or bronchopneumonia.

Other relatively common etiologies are congenital heart disease and trauma. Pulmonary hypertension secondary to cardiac disease is a prominent etiology for hemoptysis in those patients without cystic fibrosis. Traumatic irritation or damage in the airway may be accidental in nature. Traumatic injury to the airway and pulmonary contusion may result from motor vehicle crashes or other direct force injuries. Bleeding can also be related to instrumentation or iatrogenic irritation of the airway as is commonly seen in a child with a tracheostomy or a child with repeated suction trauma to the upper airway. Children who have been victims of nonaccidental trauma or deliberate suffocation can also be found to have blood in the mouth or airway (see Chapter 40). Fictitious hemoptysis may rarely be encountered in the setting of Factitious Disorder by Proxy (formerly Munchausen's by proxy; see Chapter 40.2).

Table 407-2 Etiology of Pulmonary Hemorrhage (Hemoptysis)*

FOCAL HEMORRHAGE
Bronchitis and bronchiectasis (especially cystic fibrosis–related)
Infection (acute or chronic), pneumonia, abscess
Tuberculosis
Trauma
Pulmonary arteriovenous malformation
Foreign body (chronic)
Neoplasm including hemangioma
Pulmonary embolus with or without infarction
Bronchogenic cysts
DIFFUSE HEMORRHAGE
Idiopathic of infancy
Congenital heart disease (including pulmonary hypertension, venoocclusive disease, congestive heart failure)
Prematurity
Cow's milk hyperreactivity (Heiner syndrome)
Goodpasture syndrome
Collagen vascular diseases (systemic lupus erythematosus, rheumatoid arthritis)
Henoch-Schönlein purpura and vasculitic disorders
Granulomatous disease (granulomatosis with polyangiitis)
Celiac disease
Coagulopathy (congenital or acquired)
Malignancy
Immunodeficiency
Exogenous toxins
Hyperammonemia
Pulmonary hypertension
Pulmonary alveolar proteinosis
Idiopathic pulmonary hemosiderosis
Tuberous sclerosis
Lymphangiomyomatosis or lymphangioleiomyomatosis
Physical injury or abuse
Catamenial

*See also Table 406-1.

Rare causes for hemoptysis include tumors and vascular anomalies such as arteriovenous malformations (Fig. 407-2). Congenital vascular malformations in the lung may also be associated with **hereditary hemorrhagic telangiectasia**. Tumors must be cautiously investigated when encountered with a flexible fiberoptic bronchoscope as bleeding may be massive and difficult to control.

Syndromes associated with vasculitic, autoimmune, and idiopathic disorders can be associated with diffuse alveolar hemorrhage (see Chapter 406).

Acute idiopathic pulmonary hemorrhage of infancy is a distinct entity and is described as an episode of pulmonary hemorrhage in a previously healthy infant born at greater than 32 wk of gestation and whose age is less than 1 yr with the following: (1) abrupt or sudden onset of overt bleeding or frank evidence of blood in the airway, (2) severe presentation leading to acute respiratory distress or failure and requiring intensive care and invasive ventilatory support, and (3) diffuse bilateral infiltration on chest radiographs or computed tomography. Prior suggestions of an association between acute idiopathic pulmonary hemorrhage of infancy and toxic mold exposure have not been supported on subsequent review.

EPIDEMIOLOGY

The frequency with which pulmonary hemorrhage occurs in the pediatric population is difficult to define. This difficulty is largely related to the variability in disease presentation. Chronic bronchiectasis as seen in cystic fibrosis (see Chapter 403) or ciliary dyskinesia (see Chapter 404) can cause hemoptysis, but usually occurs in children older than 10 yr of age. The incidence of pulmonary hemorrhage may be significantly underestimated because many children and young adults swallow rather than expectorate mucus, a behavior that may prevent recognition of hemoptysis, the primary presenting symptom of the disorder.

PATHOPHYSIOLOGY

Pulmonary hemorrhage can be localized or diffuse. Focal hemorrhage from an isolated bronchial lesion is often secondary to infection or chronic inflammation. Erosion through a chronically inflamed airway into the adjacent bronchial artery is a mechanism for potentially massive hemorrhage. Bleeding from such a lesion is more likely to be bright red, brisk, and secondary to enlarged bronchial arteries and systemic arterial pressures. The severity of more diffuse hemorrhage can be difficult to ascertain. The rate of blood loss may be insufficient to reach the proximal airways. Therefore, the patient may present without hemoptysis. The diagnosis of pulmonary hemorrhage is generally achieved by finding evidence of blood or hemosiderin in the lung. Within 48-72 hr of an episode of bleeding, alveolar macrophages convert the iron from erythrocytes into hemosiderin. It may take weeks to clear these hemosiderin-laden macrophages completely from the alveolar spaces. This fact may allow differentiation between acute and chronic hemorrhage. Hemorrhage is often followed by the influx of neutrophils and other proinflammatory mediators. With repeated or chronic hemorrhage, pulmonary fibrosis can become a prominent pathologic finding.

CLINICAL MANIFESTATIONS

The severity of presentation in patients with hemoptysis and pulmonary hemorrhage is highly variable. Older children and young adults with a focal hemorrhage may complain of warmth or a "bubbling" sensation in the chest wall. This can occasionally aid the clinician in locating the area involved. Rapid and large-volume blood loss manifests as symptoms of cyanosis, respiratory distress, and shock. Chronic, subclinical blood loss may manifest as anemia, fatigue, dyspnea, or altered activity tolerance. Less commonly, patients present with persistent infiltrates on chest radiograph or symptoms of chronic illness such as failure to thrive.

Pulmonary arteriovenous malformations may present with hemoptysis, hemothorax, a round localized mass on x-ray or CT, clubbing, cyanosis, or embolic phenomenon.

LABORATORY FINDINGS AND DIAGNOSIS

A patient with suspected hemorrhage should have a laboratory evaluation with complete blood count and coagulation studies. The complete blood count result may demonstrate a microcytic, hypochromic anemia but may be normal early in an acute bleeding episode. If iron stores are sufficient, a reticulocytosis may be present. Other laboratory findings are highly dependent on the underlying diagnosis. A urinalysis may show evidence of nephritis in patients with a comorbid pulmonary renal syndrome. The classic and definitive finding in pulmonary hemorrhage is that of **hemosiderin-laden macrophages** in pulmonary secretions. Hemosiderin-laden macrophages may be detected by sputum analysis with Prussian blue staining when a patient is able to successfully expectorate sputum from the lower airways. In younger children, or in weak or neurodevelopmentally compromised patients unable to expectorate sputum, induced sputum may provide an acceptable specimen; alternatively, a flexible bronchoscopy with **bronchoalveolar lavage** may be required for specimen retrieval.

Chest radiographs may demonstrate fluffy bilateral densities, as seen in acute idiopathic pulmonary hemorrhage of infancy (Fig. 407-3) or the patchy consolidation seen in idiopathic pulmonary hemosiderosis (Fig. 407-4). Alveolar infiltrates seen on chest radiograph may be regarded as a representation of recent bleeding, but their absence does not rule out the occurrence of pulmonary hemorrhage. Infiltrates, when present, are often symmetric and diffuse and may be preferentially located in the perihilar regions and lower lobes. The costophrenic angles and lung apices are frequently spared. CT may be indicated to assess for underlying disease processes.

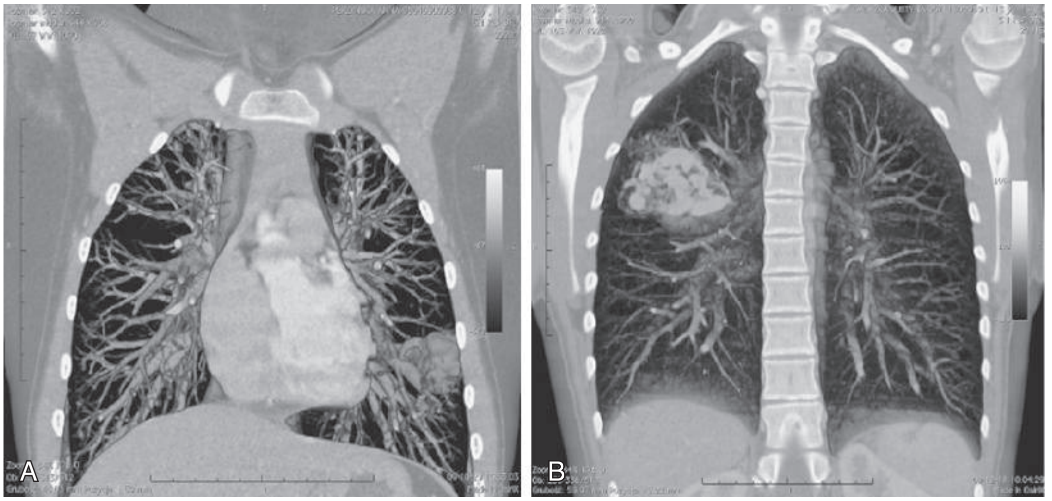

Figure 407-2 **A,** Volume-rendering reconstruction of the contrast-enhanced spiral CT showing a large arteriovenous fistula in the left upper lobe (lingula). **B,** Volume-rendering reconstruction of the contrast-enhanced spiral CT showing an arteriovenous fistula in the right upper lobe. *(From Grzela K, Krenke K, Kulus M: Pulmonary arteriovenous malformations: clinical and radiological presentation.* J Pediatr *158:856, 2011, Figs. 1 and 2, p. 856.)*

Figure 407-3 Radiographic appearance of acute idiopathic pulmonary hemorrhage in infancy. *(From Brown CM, Redd SC, Damon SA; Centers for Disease Control and Prevention [CDC]: Acute idiopathic pulmonary hemorrhage among infants: recommendations from the Working Group for Investigation and Surveillance,* MMWR Recomm Rep *53:1–12, 2004.)*

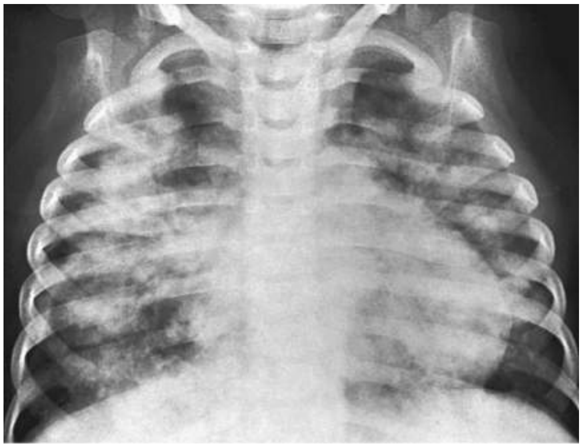

Figure 407-4 Diffuse pulmonary hemorrhage that was thought to be the result of idiopathic pulmonary hemosiderosis in a 3 yr old boy. Frontal radiograph reveals bilateral airspace consolidation that is patchy. Tracheal washing contained large numbers of macrophages filled with hemosiderin. Ten days later, most of the consolidative changes in the lungs had cleared. The patient's anemia was successfully treated with blood transfusion. *(From Slovis T, editor:* Caffey's pediatric diagnostic imaging, *ed 11, Philadelphia, 2008, Mosby/Elsevier; courtesy of Bertram Girdany, MD, Pittsburgh, PA.)*

Lung biopsy is rarely necessary unless bleeding is chronic or an etiology cannot be determined with other methods. Pulmonary function testing, including a determination of gas exchange, is important to assess the severity of the ventilatory defect. In older children, spirometry may demonstrate evidence of predominantly obstructive disease in the acute period. Restrictive disease secondary to fibrosis is typically seen with more chronic disease. Diffusion capacity of carbon monoxide measurements are typically elevated in the setting of pulmonary hemorrhage because of the strong affinity of the intra-alveolar hemoglobin for carbon monoxide.

TREATMENT

In the setting of massive blood loss, volume resuscitation and transfusion of blood products are necessary. Maintenance of adequate ventilation and circulatory function is crucial. Rigid bronchoscopy may be utilized for localization of bleeding and for removal of debris but active bleeding may be exacerbated by airway manipulation. Flexible bronchoscopy and bronchoalveolar lavage may be required for diagnosis. Ideally, treatment is directed at the specific pathologic process responsible for the hemorrhage. When bronchiectasis is a known entity and a damaged artery can be localized, bronchial artery embolization is often the therapy of choice. If embolization fails, total or partial lobectomy may be required. Embolization is the initial treatment of choice for an arteriovenous malformation. In circumstances of diffuse hemorrhage, corticosteroids and other immunosuppressive agents have been shown to be of benefit. Prognosis depends largely on the underlying disease process and the chronicity of bleeding.

Chapter 408
Atelectasis

Ranna A. Rozenfeld

Atelectasis is the incomplete expansion or complete collapse of air-bearing tissue, resulting from obstruction of air intake into the alveolar sacs. Segmental, lobar, or whole lung collapse is associated with the absorption of air contained in the alveoli, which are no longer ventilated.

PATHOPHYSIOLOGY

The causes of atelectasis can be divided into 5 groups (Table 408-1). Respiratory syncytial virus (see Chapter 260) and other viral infections, including influenza viruses in young children can cause multiple areas of atelectasis. Mucous plugs are a common predisposing factor to atelectasis. Massive collapse of 1 or both lungs is most often a postoperative complication but occasionally results from other causes, such as trauma, asthma, pneumonia, tension pneumothorax (see Chapter 411), aspiration of foreign material (see Chapters 387 and 397), and paralysis, or after extubation. Massive atelectasis is usually produced by a combination of factors, including immobilization or decreased use of the diaphragm and the respiratory muscles, obstruction of the bronchial tree, and abolition of the cough reflex.

CLINICAL MANIFESTATIONS

Symptoms vary with the cause and extent of the atelectasis. A small area is likely to be asymptomatic. When a large area of previously normal lung becomes atelectatic, especially when it does so suddenly, dyspnea accompanied by rapid shallow respirations, tachycardia, cough, and often cyanosis occurs. If the obstruction is removed, the symptoms disappear rapidly. Although it was once believed that atelectasis alone can cause fever, studies have shown no association between atelectasis and fever. Physical findings include limitation of chest excursion, decreased breath sound intensity, and coarse crackles. Breath sounds are decreased or absent over extensive atelectatic areas.

Table 408-1 Anatomic Causes of Atelectasis

CAUSE	CLINICAL EXAMPLES
External compression on the pulmonary parenchyma	Pleural effusion, pneumothorax, intrathoracic tumors, diaphragmatic hernia
Endobronchial obstruction completely obstructing the ingress of air	Enlarged lymph node, tumor, cardiac enlargement, foreign body, mucoid plug, broncholithiasis
Intraluminal obstruction of a bronchus	Foreign body, asthma, granulomatous tissue, tumor, secretions including mucous plugs, bronchiectasis, pulmonary abscess, chronic bronchitis, acute laryngotracheobronchitis, plastic bronchitis
Intrabronchiolar obstruction	Bronchiolitis, interstitial pneumonitis, asthma
Respiratory compromise or paralysis	Neuromuscular abnormalities, osseous deformities, overly restrictive casts and surgical dressings, defective movement of the diaphragm, or restriction of respiratory effort

Massive pulmonary atelectasis usually presents with dyspnea, cyanosis, and tachycardia. An affected child is extremely anxious and, if old enough, complains of chest pain. The chest appears flat on the affected side, where decreased respiratory excursion, dullness to percussion, and feeble or absent breath sounds are also noted. Postoperative atelectasis usually manifests within 24 hr of operation but may not occur for several days.

Acute lobar collapse is a frequent occurrence in patients receiving intensive care. If undetected, it can lead to impaired gas exchange, secondary infection, and subsequent pulmonary fibrosis. Initially, hypoxemia may result from ventilation-perfusion mismatch. In contrast to atelectasis in adult patients, in whom the lower lobes and, in particular, the left lower lobe are most often involved, 90% of cases in children involve the upper lobes and 63% involve the right upper lobe. There is also a high incidence of upper lobe atelectasis and, especially, right upper lobe collapse in patients with atelectasis being treated in neonatal intensive care units. This high incidence may be a result of movement of the endotracheal tube into the right mainstem bronchus, where it obstructs or causes inflammation of the bronchus to the right upper lobe.

DIAGNOSIS

The diagnosis of atelectasis can usually be established by chest radiographic examination. Typical findings include volume loss and displacement of fissures. Atypical presentations include atelectasis manifesting as a mass like opacity and atelectasis in an unusual location. Lobar atelectasis may be associated with pneumothorax.

In asthmatic children, chest radiography demonstrates an abnormality rate of 44%, compared with a thorax high-resolution CT scan abnormality rate of 75%. Children with asthma and atelectasis have an increased incidence of right middle lobe syndrome, acute asthma exacerbations, pneumonia, and upper airway infections.

In foreign-body aspiration, atelectasis is one of the most common radiographic findings. The site of atelectasis usually indicates the site of the foreign body (see Chapter 377.1). Atelectasis is more common when diagnosis of foreign-body aspiration is delayed for greater than 2 wk.

Bronchoscopic examination reveals a collapsed main bronchus when the obstruction is at the tracheobronchial junction and may also disclose the nature of the obstruction.

Massive pulmonary atelectasis is generally diagnosed on chest radiograph. Typical findings include elevation of the diaphragm, narrowing of the intercostal spaces, and displacement of the mediastinal structures and heart toward the affected side (Fig. 408-1).

TREATMENT

Treatment depends on the cause of the collapse. If effusion or pneumothorax is responsible, the external compression must first be removed. Often vigorous efforts at cough, deep breathing, and percussion will facilitate expansion. Aspiration with sterile tracheal catheters may facilitate removal of mucous plugs. Continuous positive airway pressure may improve atelectasis.

Bronchoscopic examination is immediately indicated if atelectasis is the result of a foreign body or any other bronchial obstruction that can be relieved. For bilateral atelectasis, bronchoscopic aspiration should also be performed immediately. It is also indicated when an isolated area of atelectasis persists for several weeks. If no anatomic basis for atelectasis is found and no material can be obtained by suctioning, the introduction of a small amount of saline followed by suctioning allows recovery of bronchial secretions for culture and, possibly, for cytologic examination. Frequent changes in the child's position, deep breathing, and chest physiotherapy may be beneficial. Intrapulmonary percussive ventilation is a chest physiotherapy technique that is safe and effective. Oxygen therapy is indicated when there is dyspnea or desaturation. Intermittent positive-pressure breathing and incentive spirometry are recommended when atelectasis does not improve after chest physiotherapy.

In some conditions, such as asthma, bronchodilator and corticosteroid treatment may accelerate atelectasis clearance. Recombinant

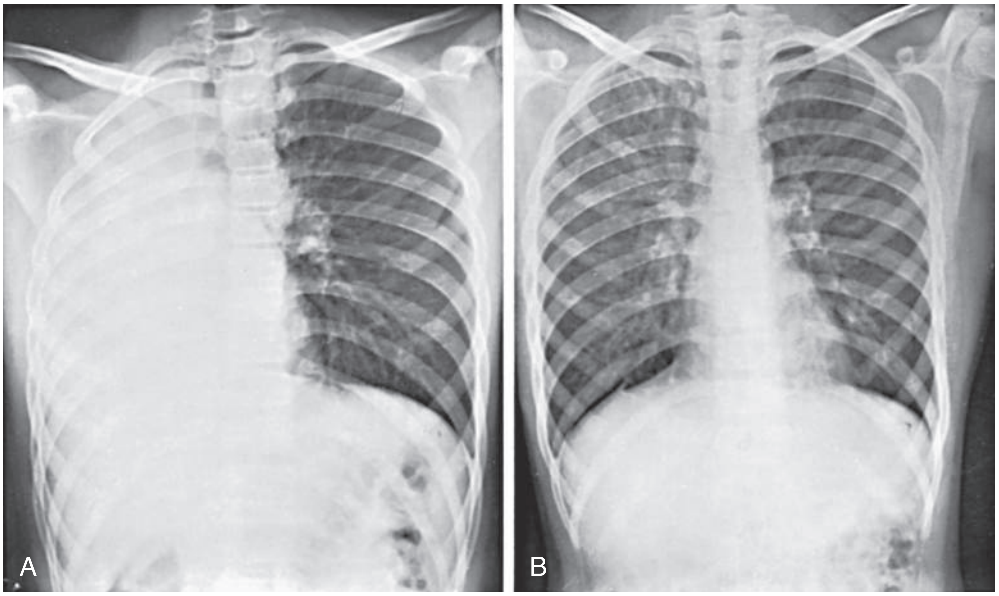

Figure 408-1 **A,** Massive atelectasis of the right lung. The patient has asthma. The heart and other mediastinal structures shift to the right during the atelectatic phase. **B,** Comparison study after reaeration subsequent to bronchoscopic removal of a mucous plug from the right mainstem bronchus.

human deoxyribonuclease, which is approved only for the treatment of cystic fibrosis, has been used off-label for patients without cystic fibrosis who have persistent atelectasis. This product reduces the viscosity of purulent bronchial debris. In patients with acute severe asthma, diffuse airway plugging with thick viscous secretions frequently occurs, with the resulting atelectasis often refractory to conventional therapy. Recombinant human deoxyribonuclease is used in both nebulized form for nonintubated patients with acute asthma as well as intratracheally for atelectasis in intubated asthmatics, with resolution of atelectasis unresponsive to conventional asthma therapies. Recombinant human deoxyribonuclease is also utilized in ventilated infants and children with atelectasis not caused by asthma.

Hypertonic saline solution increases mucociliary clearance in patients with asthma, bronchiectasis, and cystic fibrosis and infants with acute bronchiolitis. It is delivered via nebulization either via face mask or endotracheal tube. It can be delivered alone or in combination with a bronchodilator. This therapy is being utilized in the outpatient and inpatient setting, as well as in both the neonatal intensive care unit and the pediatric intensive care unit, to help facilitate airway clearance.

Lobar atelectasis in cystic fibrosis is discussed in Chapter 403.

Atelectasis can occur in patients with neuromuscular diseases. These patients tend to have ineffective cough and difficulty expelling respiratory tract secretions, which lead to pneumonia and atelectasis. Several devices and treatments are available to assist these patients, including intermittent positive-pressure breathing, a mechanical insufflator–exsufflator, and noninvasive bilevel positive-pressure ventilation via nasal mask or full-face mask. Patients with neuromuscular disease who have undergone surgery are at substantial risk for postoperative atelectasis and subsequent pneumonia. Migrating atelectasis in the newborn infant, a rare and unique presentation, may be secondary to neuromuscular disease.

There is an association between the development of lobar collapse and the requirement for mechanical ventilation. Although lobar collapse is rarely a cause of long-term morbidity, its occurrence may necessitate the prolongation of mechanical ventilation or re-intubation.

Table 408-2	Benefit of Airway Clearance Therapies in Pediatric Conditions
CLEAR AND PROVEN BENEFIT Cystic fibrosis	
PROBABLE BENEFIT Neuromuscular disease Cerebral palsy Atelectasis in children undergoing mechanical ventilation	
POSSIBLE BENEFIT Prevention of postextubation atelectasis in neonates	
MINIMAL TO NO BENEFIT Acute asthma Bronchiolitis Hyaline membrane disease Respiratory failure without atelectasis Prevention of atelectasis immediately following surgery	

From Schechter MS: Airway clearance applications in infants and children, Respir Care *52:1382–1390, 2007.*

In ventilated patients, positive end-expiratory pressure or continuous positive airway pressure is generally indicated.

Airway clearance therapies utilized for adults are often recommended and/or utilized in pediatric populations. However, given the differences in respiratory physiology and anatomy between children and adults, practices applicable to one may or may not apply to the other. Atelectasis caused by cystic fibrosis is the only pediatric entity that clearly benefits from airway clearance therapy, although atelectasis caused by neuromuscular disease, cerebral palsy, or mechanical ventilation probably benefits from such therapy (Table 408-2). Thus far no specific airway clearance therapy has been demonstrated to be superior.

Chapter **409**

Pulmonary Tumors

Susanna A. McColley

ETIOLOGY

Primary tumors of the lung are rare in children and adolescents. An accurate estimate of frequency is currently not possible because the literature is composed of case reports and case series. A high incidence of "inflammatory pseudotumors" further clouds the statistics. **Bronchial adenomas (including bronchial carcinoid, adenoid cystic carcinoma** and **mucoepidermoid carcinomas)** are the most common primary tumors; bronchial carcinoid tumors represent ≈80%. Carcinoids are low-grade malignancies; carcinoid syndrome is rare in children. Metastatic lesions are the most common forms of pulmonary malignancy in children; primary processes include Wilms tumor, osteogenic sarcoma, and hepatoblastoma (see Part XXII: Cancer and Benign Tumors). Adenocarcinoma and undifferentiated histology are the most common pathologic findings in primary lung cancer; pulmonary blastoma is rarer and frequently occurs in the setting of cystic lung disease. Mediastinal involvement with lymphoma is more common than primary pulmonary malignancies.

CLINICAL MANIFESTATIONS AND EVALUATION

Pulmonary tumors may manifest as fever, hemoptysis, wheezing, cough, pleural effusion, chest pain, dyspnea, or recurrent or persistent pneumonia or atelectasis. Localized wheezing, and wheezing unresponsive to bronchodilators, can occur with bronchial tumors. Tumors may be suspected from plain chest radiographs; CT scanning of the chest is necessary for precise anatomic definition (Fig. 409-1). Depending on the tumor size and location, pulmonary function tests may be normal or show an obstructive, restrictive, or mixed pattern; as with the physical exam, there is no responsiveness to bronchodilators. Bronchial tumors are occasionally diagnosed during fiberoptic bronchoscopy performed for persistent or recurrent pulmonary infiltrates or for hemoptysis.

Patients with symptoms or with radiographic or other laboratory findings suggesting pulmonary malignancy should be evaluated carefully for a tumor at another site before surgical excision is carried out. Isolated primary lesions and isolated metastatic lesions discovered long after the primary tumor has been removed are best treated by excision. The prognosis varies and depends on the type of tumor involved; outcomes for inflammatory pseudotumors and primary pulmonary carcinoid tumors treated with resection are good.

Chapter 410

Pleurisy, Pleural Effusions, and Empyema

Glenna B. Winnie and Steven V. Lossef

Pleurisy is the inflammation of the pleura; it may be accompanied by an effusion. The most common cause of pleural effusion in children is bacterial pneumonia (see Chapter 400); heart failure (see Chapter 442), rheumatologic causes, and metastatic intrathoracic malignancy are the next most common causes. A variety of other diseases account for the remaining cases, including tuberculosis (see Chapter 215), lupus erythematosus (see Chapter 158), aspiration pneumonitis (see Chapter 397), uremia, pancreatitis, subdiaphragmatic abscess, and rheumatoid arthritis. Males and females are affected equally.

Inflammatory processes in the pleura are usually divided into 3 types: dry or plastic, serofibrinous or serosanguineous, and purulent pleurisy or empyema.

410.1 Dry or Plastic Pleurisy (Pleural Effusion)

Glenna B. Winnie and Steven V. Lossef

ETIOLOGY

Plastic pleurisy may be associated with acute bacterial or viral pulmonary infections or may develop during the course of an acute upper respiratory tract illness. The condition is also associated with tuberculosis and connective tissue diseases such as rheumatic fever.

PATHOLOGY AND PATHOGENESIS

The process is usually limited to the visceral pleura, with small amounts of yellow serous fluid and adhesions between the pleural surfaces. In tuberculosis, the adhesions develop rapidly and the pleura are often thickened. Occasionally, fibrin deposition and adhesions are severe enough to produce a fibrothorax that markedly inhibits the excursions of the lung.

CLINICAL MANIFESTATIONS

The primary disease often overshadows signs and symptoms. Pain, the principal symptom, is exaggerated by deep breathing, coughing, and straining. Occasionally, pleural pain is described as a dull ache, which is less likely to vary with breathing. The pain is often localized over the chest wall and is referred to the shoulder or the back. Pain with breathing is responsible for grunting and guarding of respirations, and the child often lies on the affected side in an attempt to decrease respiratory excursions. Early in the illness, a leathery, rough, inspiratory and expiratory friction rub may be audible, but it usually disappears rapidly. If the layer of exudate is thick, increased dullness to percussion and decreased breath sounds may be heard. Pleurisy may be asymptomatic. Chronic pleurisy is occasionally encountered with conditions such as atelectasis, pulmonary abscess, connective tissue diseases, and tuberculosis.

LABORATORY FINDINGS

Plastic pleurisy may be detected on radiographs as a diffuse haziness at the pleural surface or a dense, sharply demarcated shadow (Figs. 410-1 and 410-2). The latter finding may be indistinguishable from small amounts of pleural exudate. Chest radiographic findings may be normal, but ultrasonography or CT findings will be positive.

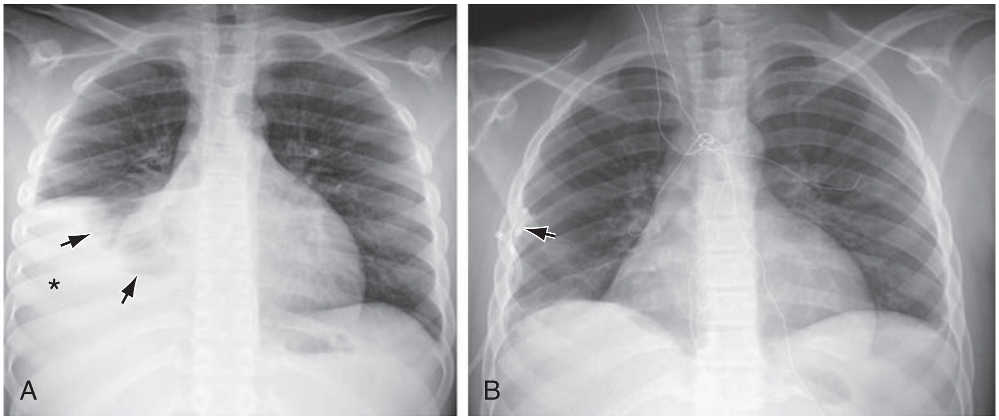

Figure 410-1 **A,** Right pleural effusion *(asterisk)* caused by lupus erythematosus in a 12 yr old child. Note compressed middle and lower lobes of the right lung *(arrows)*. **B,** The effusion was evacuated and the right lung was completely reexpanded after insertion of the pigtail chest tube *(arrow)*.

Chakrabarti B, Davies PD: Pleural tuberculosis, *Monaldi Arch Chest Dis* 65(1):26–33, 2006.

Kass SM, Williams PM, Reamy BV: Pleurisy, *Am Fam Physician* 75:1357–1364, 2007.

DIFFERENTIAL DIAGNOSIS

Plastic pleurisy must be distinguished from other diseases, such as epidemic pleurodynia, trauma to the rib cage (rib fracture), lesions of the dorsal root ganglia, tumors of the spinal cord, herpes zoster, gallbladder disease, and trichinosis. Even if evidence of pleural fluid is not found on physical or radiographic examination, a CT- or ultrasound-guided pleural tap in suspected cases often results in the recovery of a small amount of exudate, which when cultured may reveal the underlying bacterial cause in patients with an acute pneumonia. Patients with pleurisy and pneumonia should always be screened for tuberculosis.

TREATMENT

Therapy should be aimed at the underlying disease. When pneumonia is present, neither immobilization of the chest with adhesive plaster nor therapy with drugs capable of suppressing the cough reflex is indicated. If pneumonia is not present or is under good therapeutic control, strapping of the chest to restrict expansion may afford relief from pain. Analgesia with nonsteroidal antiinflammatory agents may be helpful.

Bibliography is available at Expert Consult.

410.2 Serofibrinous or Serosanguineous Pleurisy (Pleural Effusion)

Glenna B. Winnie

ETIOLOGY

Serofibrinous pleurisy is defined by a fibrinous exudate on the pleural surface and an exudative effusion of serous fluid into the pleural cavity. Generally it is associated with infections of the lung or with inflammatory conditions of the abdomen or mediastinum; occasionally, it is found with connective tissue diseases such as lupus erythematosus, periarteritis, and rheumatoid, arthritis, and it may be seen with primary or metastatic neoplasms of the lung, pleura, or mediastinum; tumors are commonly associated with a hemorrhagic pleurisy.

PATHOGENESIS

Pleural fluid originates from the capillaries of the parietal pleura and is absorbed from the pleural space via pleural stomas and the lymphatics of the parietal pleura. The rate of fluid formation is dictated by the Starling law, by which fluid movement is determined by the balance of hydrostatic and osmotic pressures in the pleural space and pulmonary capillary bed, and the permeability of the pleural membrane. Normally, only 4-12 mL of fluid is present in the pleural space, but if formation exceeds clearance, fluid accumulates. Pleural inflammation increases the permeability of the plural surface, with increased proteinaceous fluid formation; there may also be some obstruction to lymphatic absorption.

CLINICAL MANIFESTATIONS

Because serofibrinous pleurisy is often preceded by the plastic type, early signs and symptoms may be those of plastic pleurisy. As fluid accumulates, pleuritic pain may disappear. The patient may become asymptomatic if the effusion remains small, or there may be only signs and symptoms of the underlying disease. Large fluid collections can produce cough, dyspnea, retractions, tachypnea, orthopnea, or cyanosis.

Physical findings depend on the amount of effusion. Dullness to flatness may be found on percussion. Breath sounds are decreased or absent, and there are a diminution in tactile fremitus, a shift of the mediastinum away from the affected side, and, occasionally, fullness of the intercostal spaces. If the fluid is not loculated, these signs may shift with changes in position. If extensive pneumonia is present, crackles and rhonchi may also be audible. Friction rubs are usually detected only during the early or late plastic stage. In infants, physical signs are less definite, and bronchial breathing may be heard instead of decreased breath sounds.

LABORATORY FINDINGS

Radiographic examination shows a generally homogeneous density obliterating the normal markings of the underlying lung. Small effusions may cause obliteration of only the costophrenic or cardiophrenic angles or a widening of the interlobar septa. Examinations should be performed with the patient both supine and upright, to demonstrate a shift of the effusion with a change in position; the decubitus position may be helpful. **Ultrasonographic** examinations are useful and may guide thoracentesis if the effusion is loculated. Examination of the fluid is essential to differentiate exudates from transudates and to determine the type of exudate. Depending on the clinical scenario, pleural fluid is sent for culture for bacterial, fungal, and mycobacterial cultures; antigen testing; Gram staining; and chemical evaluation of content, including protein, lactic dehydrogenase and glucose, amylase, specific gravity, total cell count and differential, cytologic examination, and pH. Complete blood count and serum chemistry analysis should be obtained; hypoalbuminemia is often present. **Exudates** usually have at least 1 of the following features: protein level >3.0 g/dL, with pleural fluid : serum protein ratio >0.5; pleural fluid lactic dehydrogenase values >200 IU/L; or fluid : serum lactic dehydrogenase ratio >0.6. Although systemic acidosis reduces the usefulness of pleural fluid pH measurements, pH <7.20 suggests an exudate (see Chapter 400). Glucose is usually <60 mg/dL in malignancy, rheumatoid disease, and tuberculosis; the finding of many small lymphocytes and a pH <7.20 suggest tuberculosis. The fluid of serofibrinous pleurisy is clear or slightly cloudy and contains relatively few leukocytes and, occasionally, some erythrocytes. Gram staining may occasionally show bacteria; however, acid-fast staining rarely demonstrates tubercle bacilli.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Thoracentesis should be performed when pleural fluid is present or is suggested, unless the effusion is small and the patient has a classic-appearing lobar pneumococcal pneumonia. Thoracentesis can differentiate serofibrinous pleurisy, empyema, hydrothorax, hemothorax, and chylothorax. Exudates are usually associated with an infectious process. In hydrothorax, the fluid has a specific gravity <1.015, and evaluation reveals only a few mesothelial cells rather than leukocytes. Chylothorax and hemothorax usually have fluid with a distinctive appearance, but differentiating serofibrinous from purulent pleurisy is impossible without microscopic examination of the fluid. Cytologic examination may reveal malignant cells. Serofibrinous fluid may rapidly become purulent.

COMPLICATIONS

Unless the fluid becomes purulent, it usually disappears relatively rapidly, particularly with appropriate treatment of bacterial pneumonia. It persists somewhat longer if a result of tuberculosis or a connective tissue disease and may recur or remain for a long time if caused by a neoplasm. As the effusion is absorbed, adhesions often develop between the 2 layers of the pleura, but usually little or no functional impairment results. Pleural thickening may develop and is occasionally mistaken for small quantities of fluid or for persistent pulmonary infiltrates. Pleural thickening may persist for months, but the process usually disappears, leaving no residua.

TREATMENT

Therapy should address the underlying disease. With a large effusion, draining the fluid makes the patient more comfortable. When a diagnostic thoracentesis is performed, as much fluid as possible should be removed for therapeutic purposes. Rapid removal of ≥1 L of pleural fluid may be associated with the development of reexpansion pulmonary edema (see Chapter 396). If the underlying disease is adequately treated, further drainage is usually unnecessary, but if sufficient fluid reaccumulates to cause respiratory embarrassment, chest tube drainage should be performed. In older children with suspected parapneumonic effusion, tube thoracostomy is considered necessary if the pleural fluid pH is <7.20 or the pleural fluid glucose level is <50 mg/dL. If the fluid is clearly purulent, tube drainage with **thrombolytic therapy** or less often video-assisted thoracoscopic surgery (VATS) is indicated.

Patients with pleural effusions may need analgesia, particularly after thoracentesis or insertion of a chest tube. Those with acute pneumonia may need supplemental oxygen in addition to specific antibiotic treatment.

Bibliography is available at Expert Consult.

410.3 Purulent Pleurisy or Empyema

Glenna B. Winnie and Steven V. Lossef

ETIOLOGY

Empyema is an accumulation of pus in the pleural space. It is most often associated with pneumonia (see Chapter 400) caused by *Streptococcus pneumoniae* (see Chapter 182), although *Staphylococcus aureus* (see Chapter 181.1) is most common in developing nations and Asia, as well as in posttraumatic empyema. The relative incidence of *Haemophilus influenzae* (see Chapter 194) empyema has decreased since the introduction of the *H. influenzae* type b vaccination. Group A streptococcus, Gram-negative organisms, tuberculosis, fungi, and malignancy are less common causes. The disease can also be produced by rupture of a lung abscess into the pleural space, by contamination introduced from trauma or thoracic surgery, or, rarely, by mediastinitis or the extension of intraabdominal abscesses.

EPIDEMIOLOGY

Empyema is most frequently encountered in infants and preschool children. It is increasing in frequency. It occurs in 5-10% of children with bacterial pneumonia and in up to 86% of children with necrotizing pneumonia.

PATHOLOGY

Empyema has 3 stages: exudative, fibrinopurulent, and organizational. During the **exudative stage**, fibrinous exudate forms on the pleural surfaces. In the **fibrinopurulent stage**, fibrinous septa form, causing loculation of the fluid and thickening of the parietal pleura. If the pus is not drained, it may dissect through the pleura into lung parenchyma, producing bronchopleural fistulas and pyopneumothorax, or into the abdominal cavity. Rarely, the pus dissects through the chest wall (i.e., empyema necessitatis). During the **organizational stage**, there is fibroblast proliferation; pockets of loculated pus may develop into thick-walled abscess cavities or the lung may collapse and become surrounded by a thick, inelastic envelope (peel).

CLINICAL MANIFESTATIONS

The initial signs and symptoms are primarily those of bacterial pneumonia. Children treated with antibiotic agents may have an interval of a few days between the clinical pneumonia phase and the evidence of empyema. Most patients are febrile, develop increased work of breathing or respiratory distress, and often appear more ill. Physical findings are identical to those described for serofibrinous pleurisy, and the 2 conditions are differentiated only by thoracentesis, which should always be performed when empyema is suspected.

LABORATORY FINDINGS

Radiographically, all pleural effusions appear similar, but the absence of a shift of the fluid with a change of position indicates a loculated empyema (Figs. 410-3 to 410-5). Septa may be confirmed by ultrasonography or CT. The maximal amount of fluid obtainable should be withdrawn by thoracentesis and studied as described in Chapter 410.2. The effusion is empyema if bacteria are present on Gram staining, the pH is <7.20, and there are >100,000 neutrophils/µL (see Chapter 400). The appearance of pus produced by different organisms is not distinctive; cultures of the fluid must always be performed. In pneumococcal empyema, the culture is positive in 58% of cases. In patients with negative culture results for pneumococcus, the pneumococcal polymerase chain reaction analysis is most helpful to making a diagnosis. Blood cultures may be positive and have a higher yield than cultures of the pleural fluid. Leukocytosis and an elevated sedimentation rate may be found.

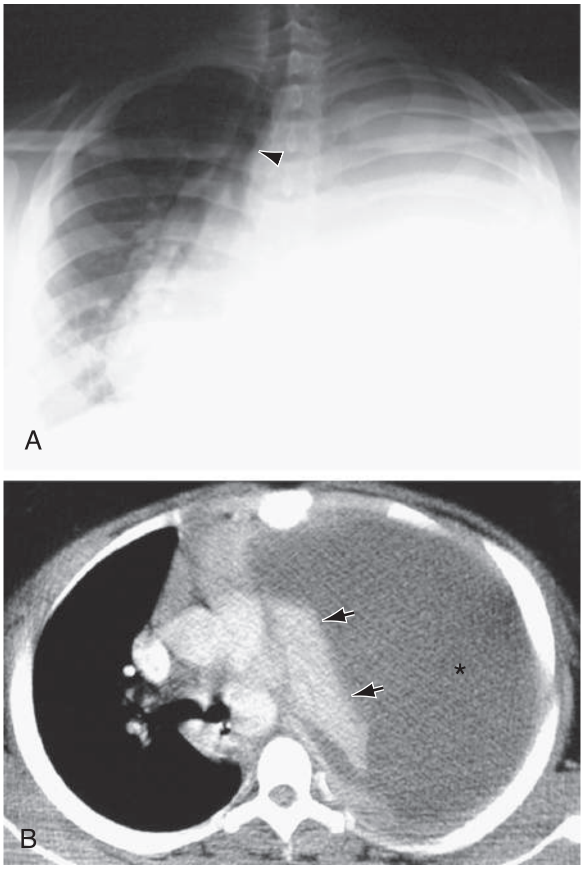

Figure 410-3 Empyema and pneumonia in a teenager. **A,** Chest radiograph shows opacification of the left thorax. Note shift of mediastinum and trachea *(arrowhead)* to right. **B,** Thoracic CT scan shows massive left pleural effusion *(asterisk)*. Note the compression and atelectasis of the left lung *(arrows)* and shift of the mediastinum to the right.

COMPLICATIONS

With staphylococcal infections, bronchopleural fistulas and pyopneumothorax commonly develop. Other local complications include purulent pericarditis, pulmonary abscesses, peritonitis from extension through the diaphragm, and osteomyelitis of the ribs. Septic complications such as meningitis, arthritis, and osteomyelitis may also occur. Septicemia is often encountered in *H. influenzae* and pneumococcal infections. The effusion may organize into a thick "peel," which may restrict lung expansion and may be associated with persistent fever and temporary scoliosis.

TREATMENT

The aim of empyema treatment is to sterilize pleural fluid and restore normal lung function. Treatment includes systemic antibiotics and thoracentesis and chest tube drainage initially with a fibrinolytic agent; if no improvement occurs, VATS is indicated. Open decortication is indicated if fibrinolysis and VATS are ineffective (see Chapter 411). If empyema is diagnosed early, antibiotic treatment plus thoracentesis achieves a complete cure. The selection of antibiotic should be based on the in vitro sensitivities of the responsible organism. See Chapters 181, 182, and 194 for treatment of infections by *Staphylococcus, S. pneumoniae*, and *H. influenzae*, respectively. Clinical response in empyema is slow; even with optimal treatment, there may be little improvement for as long as 2 wk. With staphylococcal infections, resolution is very slow, and systemic antibiotic therapy is required for 3-4 wk. Instillation of antibiotics into the pleural cavity does not improve results.

When pus is obtained by thoracentesis, closed-chest tube drainage with fibrolytics is the initial procedure followed by VATS if there is no improvement. Multiple aspirations of the pleural cavity should not be attempted. If pleural fluid septa are detected on ultrasound, fibrinolysis is attempted followed by VATS if no improvement is noted. Closed-chest tube drainage is controlled by an underwater seal or continuous suction; sometimes more than 1 tube is required to drain loculated areas. Closed drainage is usually continued for 5-7 days. Chest tubes that are no longer draining are removed.

Instillation of fibrinolytic agents into the pleural cavity via the chest tube may promote drainage, decrease fever, lessen need for surgical intervention, and shorten hospitalization; it does not shorten the course of disease when used after VATS. The optimal drug and dosage have not been determined. Streptokinase 15,000 units/kg in 50 mL of 0.9% saline daily for 3-5 days and urokinase 40,000 units in 40 mL saline every 12 hr for 6 doses have been evaluated in randomized trials in children. Alteplase (tissue plasminogen activator) has also been used. There is a risk of anaphylaxis with streptokinase, and all 3 drugs can be associated with hemorrhage and other complications.

Extensive fibrinous changes may take place over the surface of the lungs owing to empyema, but they eventually resolve. In the child who remains febrile and dyspneic for more than 72 hr after initiation of therapy with intravenous antibiotics and thoracostomy tube drainage, surgical decortication via VATS or, less often, open thoracotomy may speed recovery. If pneumatoceles form, no attempt should be made to treat them surgically or by aspiration, unless they reach sufficient size to cause respiratory embarrassment or become secondarily infected. Pneumatoceles usually resolve spontaneously with time. The long-term clinical prognosis for adequately treated empyema is excellent, and follow-up pulmonary function studies suggest that residual restrictive disease is uncommon, with or without surgical intervention.

Chapter 411

Pneumothorax

Glenna B. Winnie and Steven V. Lossef

Pneumothorax is the accumulation of extrapulmonary air within the chest, most commonly from leakage of air from within the lung. Air leaks can be primary or secondary and can be spontaneous, traumatic, iatrogenic, or catamenial (Table 411-1). Pneumothorax in the neonatal period is also discussed in Chapter 101.12.

ETIOLOGY AND EPIDEMIOLOGY

A **primary spontaneous pneumothorax** occurs without trauma or underlying lung disease. Spontaneous pneumothorax with or without

Table 411-1 Causes of Pneumothorax in Children

SPONTANEOUS
Primary idiopathic—usually resulting from ruptured subpleural blebs
Secondary blebs
Congenital lung disease:
Congenital cystic adenomatoid malformation
Bronchogenic cysts
Pulmonary hypoplasia*
Birt-Hogg-Dube syndrome
Conditions associated with increased intrathoracic pressure:
Asthma
Bronchiolitis
Air-block syndrome in neonates
Cystic fibrosis
Airway foreign body
Smoking (cigarettes, marijuana, crack cocaine)
Infection:
Pneumatocele
Lung abscess
Echinococcosis
Bronchopleural fistula
Diffuse lung disease:
Langerhans cell histiocytosis
Tuberous sclerosis
Marfan syndrome
Ehlers-Danlos syndrome
Metastatic neoplasm—usually osteosarcoma (rare)
Pulmonary blastoma
TRAUMATIC
Noniatrogenic
Penetrating trauma
Blunt trauma
High-flow therapy
Loud music (air pressure)
Iatrogenic
Thoracotomy
Thoracoscopy, thoracentesis
Tracheostomy
Tube or needle puncture
Mechanical ventilation

*Associated with renal agenesis, diaphragmatic hernia, amniotic fluid leaks.
From Kuhn JP, Slovis TL, Haller JO, editors: Caffey's pediatric diagnostic imaging, *ed 10, Philadelphia, 2004, Mosby.*

exertion occurs occasionally in teenagers and young adults, most frequently in males who are tall, thin, and thought to have subpleural blebs. Familial cases of spontaneous pneumothorax occur and have been associated with mutations in the folliculin gene (*FCLN*). *FCLN* mutations may be seen in the Birt-Hogg-Dube syndrome (skin fibrofolliculomas, multiple basal lung cysts, renal malignancies) or in patients with familial or recurrent spontaneous pneumothoraces. Patients with collagen synthesis defects, such as Ehlers-Danlos disease (see Chapter 659) and Marfan syndrome (see Chapter 702) are unusually prone to the development of pneumothorax.

A pneumothorax arising as a complication of an underlying lung disorder but without trauma is a **secondary spontaneous pneumothorax.** Pneumothorax can occur in pneumonia, usually with empyema; it can also be secondary to pulmonary abscess, gangrene, infarct, rupture of a cyst or an emphysematous bleb (in asthma), or foreign bodies in the lung. In infants with staphylococcal pneumonia, the incidence of pneumothorax is relatively high. It is found in ≈5% of hospitalized asthmatic children and usually resolves without treatment. Pneumothorax is a serious complication in cystic fibrosis (see Chapter 403). Pneumothorax also occurs in patients with lymphoma or other malignancies, and in graft-versus-host disease with bronchiolitis obliterans.

External chest or abdominal blunt or penetrating trauma can tear a bronchus or abdominal viscus, with leakage of air into the pleural space. Ecstasy (methylenedioxymethamphetamine), crack cocaine, and marijuana abuse are associated with pneumothorax.

Iatrogenic pneumothorax can complicate transthoracic needle aspiration, tracheotomy, subclavian line placement, thoracentesis, or transbronchial biopsy. It may occur during mechanical or noninvasive ventilation, high-flow nasal cannula therapy, acupuncture, and other diagnostic or therapeutic procedures.

Catamenial pneumothorax, an unusual condition that is related to menses, is associated with diaphragmatic defects and pleural blebs.

Pneumothorax can be associated with a serous effusion (hydropneumothorax), a purulent effusion (pyopneumothorax), or blood (hemopneumothorax). Bilateral pneumothorax is rare after the neonatal period but has been reported after lung transplantation and with *Mycoplasma pneumoniae* infection and tuberculosis.

PATHOGENESIS

The tendency of the lung to collapse, or elastic recoil, is balanced in the normal resting state by the inherent tendency of the chest wall to expand outward, creating negative pressure in the intrapleural space. When air enters the pleural space, the lung collapses. Hypoxemia occurs because of alveolar hypoventilation, ventilation–perfusion mismatch, and intrapulmonary shunt. In simple pneumothorax, intrapleural pressure is atmospheric, and the lung collapses up to 30%. In complicated, or tension, pneumothorax, continuing leak causes increasing positive pressure in the pleural space, with further compression of the lung, shift of mediastinal structures toward the contralateral side, and decreases in venous return and cardiac output.

CLINICAL MANIFESTATIONS

The onset of pneumothorax is usually abrupt, and the severity of symptoms depends on the extent of the lung collapse and on the amount of preexisting lung disease. Pneumothorax may cause dyspnea, pain, and cyanosis. When it occurs in infancy, symptoms and physical signs may be difficult to recognize. Moderate pneumothorax may cause little displacement of the intrathoracic organs and few or no symptoms. The severity of pain usually does not directly reflect the extent of the collapse.

Usually, there is respiratory distress, with retractions, markedly decreased breath sounds, and a tympanitic percussion note over the involved hemithorax. The larynx, trachea, and heart may be shifted toward the unaffected side. When fluid is present, there is usually a sharply limited area of tympany above a level of flatness to percussion. The presence of amphoric breathing or, when fluid is present in the pleural cavity, of gurgling sounds synchronous with respirations suggests an open fistula connecting with air-containing tissues.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of pneumothorax is usually established by radiographic examination (Figs. 411-1 to 411-6). The amount of air outside the lung varies with time. A radiograph that is taken early shows less lung collapse than one taken later if the leak continues. Expiratory views accentuate the contrast between lung markings and the clear area of the pneumothorax (see Fig. 411-1). When the possibility of diaphragmatic hernia is being considered, a small amount of barium may be necessary to demonstrate that it is not free air but is a portion of the gastrointestinal tract that is in the thoracic cavity. Ultrasound can also be used to establish the diagnosis.

It may be difficult to determine whether a pneumothorax is under tension. **Evidence of tension** includes shift of mediastinal structures away from the side of the air leak. A shift may be absent in situations in which the other hemithorax resists the shift, such as in the case of bilateral pneumothorax. When the lungs are both stiff, such as in cystic fibrosis or respiratory distress syndrome, the unaffected lung may not collapse easily and shift may not occur (see Fig. 411-3). On occasion, the diagnosis of tension pneumothorax is made only on the basis of evidence of circulatory compromise or on hearing a "hiss" of rapid exit of air under tension with the insertion of the thoracostomy tube.

Pneumothorax must be differentiated from localized or generalized emphysema, an extensive emphysematous bleb, large pulmonary cavities or other cystic formations, diaphragmatic hernia, compensatory overexpansion with contralateral atelectasis, and gaseous distention of

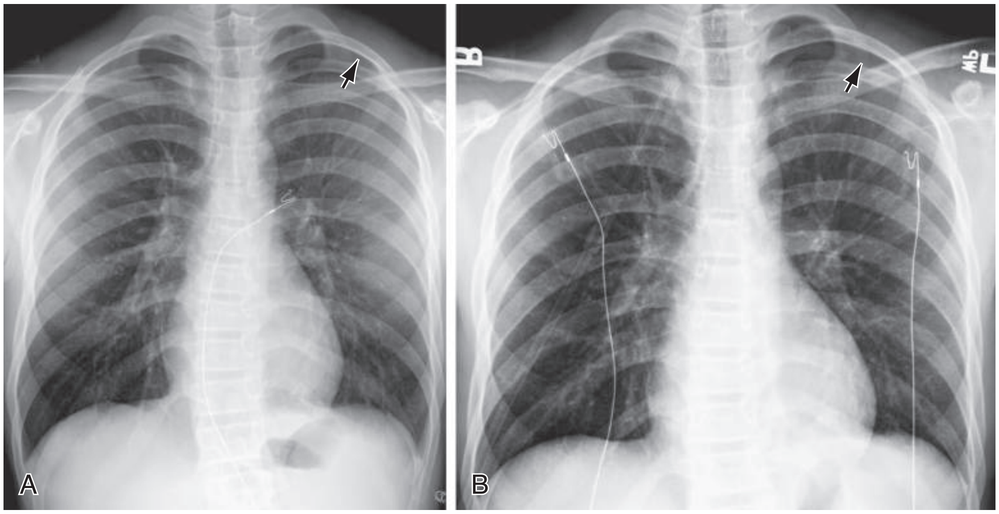

Figure 411-1 Utility of an expiratory film in detection of a small pneumothorax. **A,** Teenage boy with stab wound and subtle radiolucency in the left apical region *(arrow)* on inspiratory chest radiograph. The margin of the visceral pleura is very faintly visible. **B,** On an expiratory film, the pneumothorax *(arrow)* is more obvious as the right lung has deflated and become more opaque, providing better contrast with the air in the pleural space.

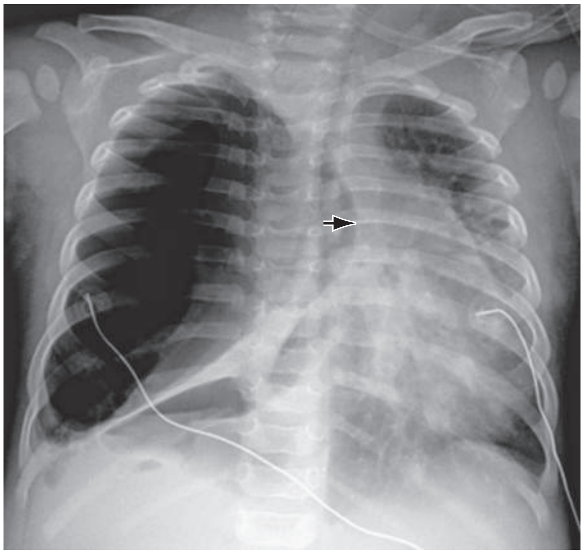

Figure 411-2 Right pneumothorax, with lung collapse of a compliant lung. Shift of the mediastinum to the left *(arrow)* indicates that this is a tension pneumothorax.

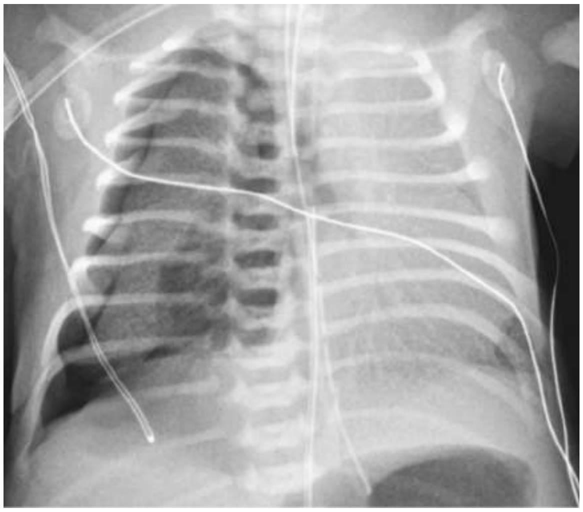

Figure 411-3 Right pneumothorax, with only limited collapse of a poorly compliant lung.

the stomach. In most cases, chest radiography or CT differentiates among these possibilities. In addition, CT may identify underlying pathology such as blebs (Fig. 411-7).

TREATMENT

Therapy varies with the extent of the collapse and the nature and severity of the underlying disease. A small (<5%) or even moderate-sized pneumothorax in an otherwise normal child may resolve without specific treatment, usually within 1 wk. A small pneumothorax complicating asthma may also resolve spontaneously. Administering 100% oxygen may hasten resolution, but patients with chronic hypoxemia should be monitored closely during administration of supplemental oxygen. Pleural pain deserves analgesic treatment. Needle aspiration may be required on an emergency basis for tension pneumothorax and is as effective as tube thoracostomy in the emergency room management of primary spontaneous pneumothorax. If the pneumothorax is recurrent, secondary, or under tension, or there is >5% collapse, chest tube drainage is necessary. Pneumothorax-complicating cystic fibrosis

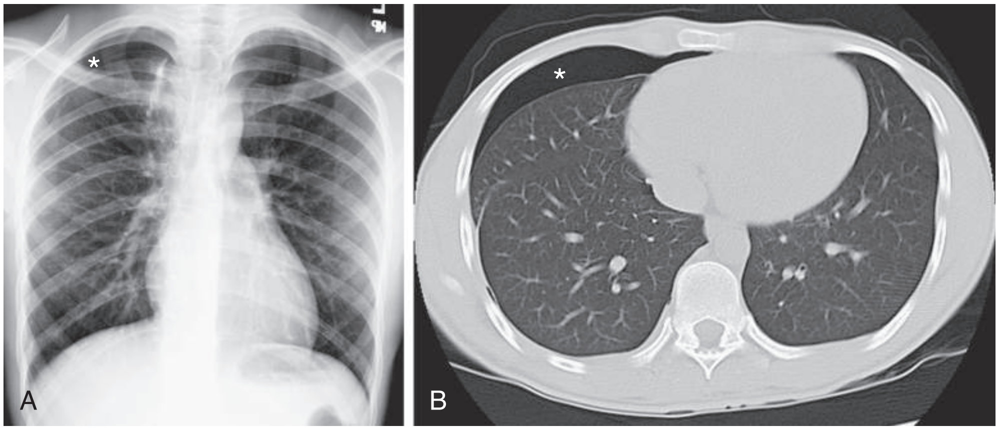

Figure 411-5 **Teenager in whom a spontaneous right pneumothorax developed because of a bleb.** He had a persistent air leak despite recent surgical resection of the causative apical bleb. Chest radiograph **(A)** and CT scan **(B)** clearly show the persistent pneumothorax *(asterisk).*

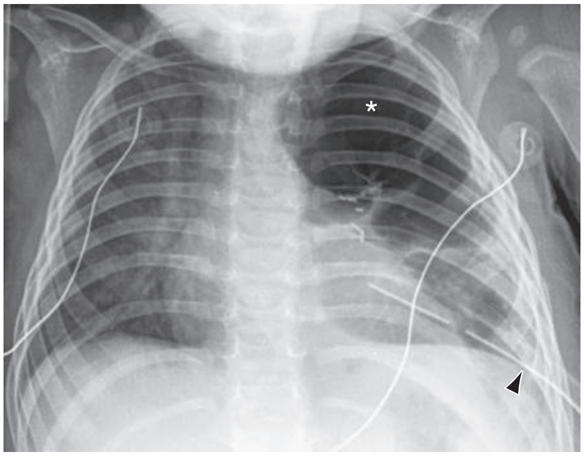

Figure 411-6 **Bronchopleural fistula following surgical resection of the left upper lobe as a result of congenital lobar emphysema.** Chest radiograph shows localized pneumothorax *(asterisk)* that persisted despite prior insertion of a large-bore chest tube *(arrowhead).*

Figure 411-7 **High-resolution CT thorax showing multiple basal cysts.** *(From Hopkins TG, Maher ER, Reid E, Marciniak S: Recurrent pneumothorax.* Lancet *377:1624, 2011, Fig. 1, p. 1624.)*

frequently recurs, and definitive treatment may be justified with the first episode. Similarly, if pneumothorax complicating malignancy does not improve rapidly with observation, chemical pleurodesis or surgical thoracotomy is often necessary. In cases with severe air leak or bronchopleural fistula, occlusion with an endobronchial balloon has been successful.

Closed thoracotomy (simple insertion of a chest tube) and drainage of the trapped air through a catheter, the external opening of which is kept in a dependent position under water, is adequate to reexpand the lung in most patients; pigtail catheters are frequently used. When there have been previous pneumothoraces, it may be indicated to induce the formation of strong adhesions between the lung and chest wall by a sclerosing procedure to prevent recurrence. This can be carried out by the introduction of talc, doxycycline, or iodopovidone into the pleural space (**chemical pleurodesis**). Open thoracotomy through a limited incision, with plication of blebs, closure of fistula, stripping of the pleura (usually in the apical lung, where the surgeon has direct vision), and basilar pleural abrasion is also an effective treatment for recurring pneumothorax. Stripping and abrading the pleura leaves raw, inflamed surfaces that heal with sealing adhesions. Postoperative pain is comparable to that with chemical pleurodesis, but the chest tube can usually be removed in 24-48 hr, compared with the usual 72 hr minimum for closed thoracotomy and pleurodesis. **Video-assisted thoracoscopic surgery** is a preferred therapy for blebectomy, pleural stripping, pleural brushing, and instillation of sclerosing agents, with somewhat less morbidity than occurs with traditional open thoracotomy. There is risk of recurrence after video-assisted thoracoscopic surgery in the pediatric population, although this is often not related to surgical failure, but rather associated with the formation of new bullae.

Pleural adhesions help prevent recurrent pneumothorax, but they also make subsequent thoracic surgery difficult. When lung transplantation may be a future consideration (e.g., in cystic fibrosis), a stepwise approach to treatment of pneumothorax has been proposed. This approach begins with observation and progresses through chest tube drainage and thoracoscopic and then open surgery, and finally to chemical or mechanical pleurodesis. At any step during this approach, the patient and family are given the option of the definitive procedure if they understand that its performance may make lung transplantation difficult or impossible. It should also be kept in mind that the longer a chest tube is in place, the greater the chance of pulmonary deterioration, particularly in a patient with cystic fibrosis, in whom strong coughing, deep breathing, and postural drainage are important. These are all difficult to accomplish with a chest tube in place.

Treatment of the underlying pulmonary disease should begin on admission and should be continued throughout the course of treatment directed at the air leak.

Chapter **412**

Pneumomediastinum

Glenna B. Winnie

Air or gas in the mediastinum is called **pneumomediastinum.**

ETIOLOGY

Typically, pneumomediastinum is caused by alveolar rupture during acute or chronic pulmonary disease. A diverse group of nonrespiratory entities can also cause it, and the lung is not always the source of the air. Lower respiratory tract infection is a common etiology for pneumomediastinum in children younger than age 7 yr, while acute asthma is the most common cause in older children and teenagers. Simultaneous pneumothorax is unusual in these patients. Pneumomediastinum has been reported after vomiting, dental extractions, adenotonsillectomy, high-flow nasal cannula therapy, normal menses, obstetric delivery, diabetes mellitus with ketoacidosis, acupuncture, anorexia nervosa, and inhalation of helium gas. It can also result from esophageal perforation (Boerhaave syndrome), penetrating chest trauma, or inhaled foreign body. Occasionally, no underlying cause is found.

PATHOGENESIS

After intrapulmonary alveolar rupture, air dissects through the perivascular sheaths and other soft tissue, planes toward the hilum, and enters the mediastinum.

CLINICAL MANIFESTATIONS

Dyspnea and transient stabbing chest pain that may radiate to the neck are the principal features of pneumomediastinum. Isolated abdominal pain, cough, and sore throat also occur. Pneumomediastinum is difficult to detect by physical examination alone. Subcutaneous emphysema, if present, is diagnostic. Cardiac dullness to percussion may be decreased, but the chests of many patients with pneumomediastinum are chronically overinflated, and it is unlikely that the clinician can be sure of this finding. A mediastinal "crunch" (Hamman sign) is occasionally heard but is easily confused with a friction rub.

LABORATORY FINDINGS

Chest radiography reveals mediastinal air, with a more distinct cardiac border than normal (Figs. 412-1 to 412-3). On the lateral projection, the posterior mediastinal structures are clearly defined, there may be a lucent ring around the right pulmonary artery, and retrosternal air can usually be seen (see Fig. 412-2). Vertical streaks of air in the mediastinum and subcutaneous air are often observed (see Fig. 412-1).

COMPLICATIONS

Pneumomediastinum is rarely a major problem in older children because the mediastinum can be depressurized by escape of air into the neck or abdomen. In the newborn, however, the rate at which air can leave the mediastinum is limited, and pneumomediastinum can lead to dangerous cardiovascular compromise or pneumothorax (see Chapters 101.12 and 411).

TREATMENT

Treatment is directed primarily at the underlying obstructive pulmonary disease or other precipitating condition. Analgesics are occasionally needed for chest pain. Rarely, subcutaneous emphysema can cause sufficient tracheal compression to justify tracheotomy; the tracheotomy also decompresses the mediastinum. Collar mediastinotomy and percutaneous drainage catheter placement are other treatment modalities.

Figure 412-3 Sail sign—thymic elevation. *(From Clark DA:* Atlas of neonatology, *ed 7, Philadelphia, 2000, WB Saunders, p. 94.)*

LABORATORY FINDINGS

The fluid is noninflammatory, has few cells, and has a lower specific gravity (<1.015) than that of a serofibrinous exudate. The ratio of pleural fluid to serum total protein is <0.5, the ratio of pleural fluid to serum lactic dehydrogenase is <0.6, and the pleural fluid lactic dehydrogenase value is less than 66% of the upper limit of the normal serum lactic dehydrogenase range.

TREATMENT

Therapy is directed at the underlying disorder; aspiration may be necessary when pressure symptoms are notable.

Bibliography is available at Expert Consult.

Chapter **413**

Hydrothorax

Glenna B. Winnie

Hydrothorax is a transudative pleural effusion; typically, it is caused by abnormal pressure gradients in the lung.

ETIOLOGY

Hydrothorax is most often associated with cardiac, renal, or hepatic disease. It can also be a manifestation of severe nutritional edema and hypoalbuminemia. Rarely, it results from vascular obstruction by neoplasms, enlarged lymph nodes, pulmonary embolism, or adhesions. It may occur from a ventriculoperitoneal shunt or peritoneal dialysis and has been reported in congenital parvovirus B19 infection.

CLINICAL MANIFESTATIONS

Hydrothorax is usually bilateral, but in cardiac disease it can be limited to the right side or greater on the right than on the left side. The physical signs are the same as those described for serofibrinous pleurisy (see Chapter 410.2), but in hydrothorax, there is more rapid shifting of the level of dullness with changes of position. It is usually associated with an accumulation of fluid in other parts of the body.

Chapter 414
Hemothorax
Glenna B. Winnie and Steven V. Lossef

Hemothorax, an accumulation of blood in the pleural cavity, is rare in children.

ETIOLOGY

Bleeding into the chest cavity most commonly occurs after chest trauma, either blunt or penetrating. It can be the result of iatrogenic trauma, including surgical procedures and venous line insertion. Hemothorax can also result from erosion of a blood vessel in association with inflammatory processes such as tuberculosis and empyema. It may complicate a variety of congenital anomalies including sequestration, patent ductus arteriosus, and pulmonary arteriovenous malformation (see Fig. 407-2 in Chapter 407). It is also an occasional manifestation of intrathoracic neoplasms, costal exostoses, blood dyscrasias, bleeding diatheses, or thrombolytic therapy. Rupture of an aneurysm is unlikely during childhood. Hemothorax may occur spontaneously in neonates and older children. A pleural hemorrhage associated with a pneumothorax is a *hemopneumothorax;* it is usually the result of a ruptured bulla with lung volume loss causing a torn pleural adhesion.

CLINICAL MANIFESTATIONS

In addition to the symptoms and signs of pleural effusion (see Chapter 410.2), hemothorax is associated with hemodynamic compromise related to the amount and rapidity of bleeding.

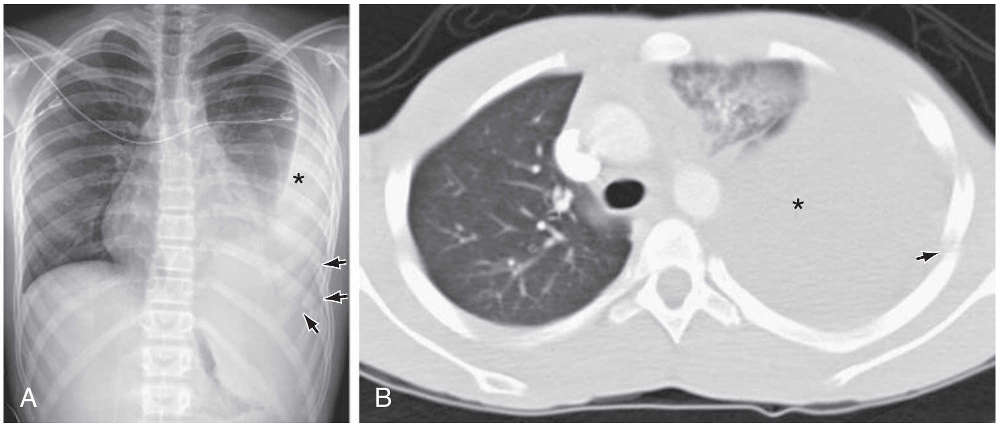

Figure 414-1 Hemothorax *(asterisk)* and associated rib fractures *(arrows)* in a teenager involved in a motor vehicle accident. **A,** Chest radiograph. **B,** CT scan.

DIAGNOSIS

The diagnosis of a hemothorax is initially suspected from radiographs or CT scans but can be made only with thoracentesis (Fig. 414-1). In every case, an effort must be made to determine and treat the cause.

TREATMENT

Initial therapy is tube thoracostomy. Surgical intervention may be required to control active bleeding, and transfusion may be indicated. Inadequate removal of blood in extensive hemothorax may lead to substantial restrictive disease secondary to organization of fibrin; fibrinolytic therapy or a decortication procedure may then be necessary. Embolization is the treatment of choice for an arteriovenous malformation.

Chapter 415
Chylothorax
Glenna B. Winnie and Steven V. Lossef

Chylothorax is a pleural collection of fluid formed by the escape of chyle from the thoracic duct or lymphatics into the thoracic cavity.

ETIOLOGY
Chylothorax in children occurs most frequently because of thoracic duct injury as a complication of cardiothoracic surgery (Fig. 415-1). Other cases are associated with chest injury (Fig. 415-2), extracorporeal membrane oxygenation, or with primary or metastatic intrathoracic malignancy (Fig. 415-3), particularly lymphoma. In newborns, rapidly increased venous pressure during delivery may lead to thoracic duct rupture. Less common causes include lymphangiomatosis; restrictive pulmonary diseases; thrombosis of the duct, superior vena cava, or subclavian vein; tuberculosis or histoplasmosis; and congenital anomalies of the lymphatic system (Fig. 415-4). Refractory chylothorax in the fetus has been associated with a missense mutation in integrin aα9 gene. Chylothorax can occur in trauma and child abuse (see Chapter 40). It is important to establish the etiology, because treatment varies with the cause. In some patients, no specific cause is identified.

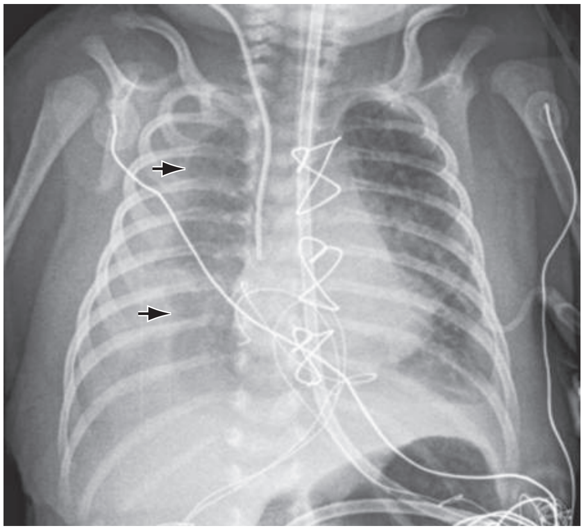

Figure 415-1 Chylothorax *(arrows)* following cardiac surgery in a 2 wk old infant.

CLINICAL MANIFESTATIONS
The signs and symptoms of chylothorax are the same as those from pleural effusion of similar size. Chyle is not irritating, so pleuritic pain is uncommon. Onset is often gradual. However, after trauma to the thoracic duct chyle may accumulate in the posterior mediastinum for days and then rupture into the pleural space with sudden onset of dyspnea, hypotension, and hypoxemia. Approximately 50% of newborns with chylothorax present with respiratory distress in the 1st day of life. Chylothorax is rarely bilateral and usually occurs on the right side.

LABORATORY FINDINGS
Thoracentesis demonstrates a chylous effusion, a milky fluid containing fat, protein, lymphocytes, and other constituents of chyle; fluid may be yellow or bloody. In newborn infants or those who are not ingesting food, the fluid may be clear. A pseudochylous milky fluid may be

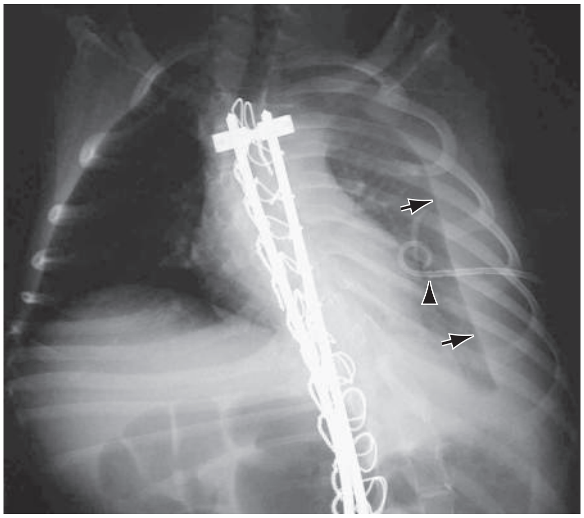

Figure 415-2 Left chylothorax *(arrows)* following spinal fusion with Harrington rods. It is postulated that the thoracic duct was injured during spine surgery. The pigtail chest tube *(arrowhead)* needed to be retracted to better drain the effusion.

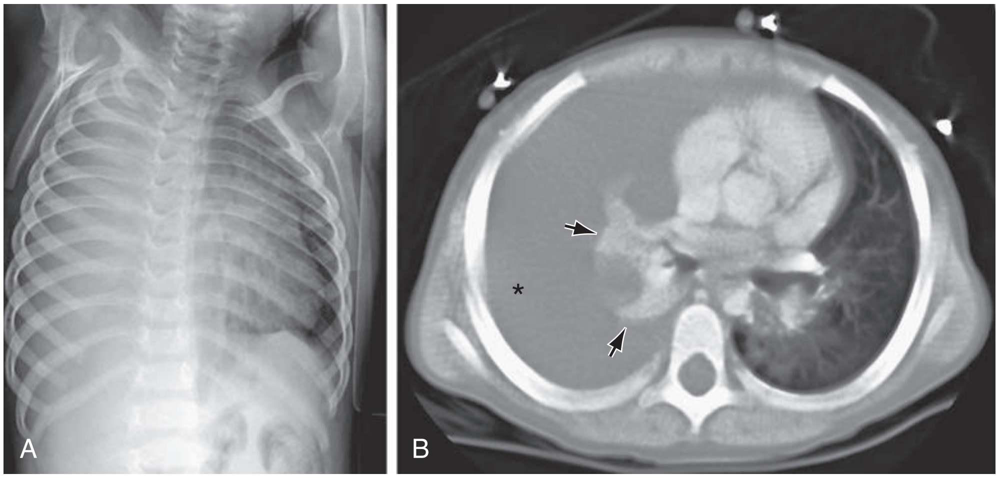

Figure 415-4 Spontaneous chylothorax in a 4 yr old with a duplication of chromosome 6. **A,** Chest radiograph shows opacification of the right thorax. **B,** CT scan shows the chylous pleural effusion *(asterisk)* compressing the atelectatic right lung *(arrows).*

present in chronic serous effusion, in which fatty material arises from degenerative changes in the fluid and not from lymph. In chylothorax, the fluid triglyceride level is >110 mg/dL, the pleural fluid:serum triglyceride ratio is >1.0, and pleural fluid:serum cholesterol ratio is <1.0; lipoprotein analysis reveals chylomicrons. Fluid immunoglobulin levels are elevated. The cells are primarily T lymphocytes. Chest radiographs show an effusion; CT scans show normal pleural thickness and may reveal a lymphoma as the etiology of the chylothorax. A lymphangiogram can localize the site of the leak, and lymphoscintigraphy may demonstrate abnormalities of the lymphatic trunks and peripheral lymphatics.

COMPLICATIONS

Repeated aspirations may be required to relieve the symptoms of pressure. Chyle reaccumulates quickly, and repeated thoracentesis may cause malnutrition with significant loss of calories, protein, and electrolytes. Immunodeficiencies, including hypogammaglobulinemia and abnormal cell-mediated immune responses, have been associated with repeated and chronic thoracenteses for chylothorax. The loss of T lymphocytes is associated with increased risk of infection in neonates; otherwise, infection is uncommon, but patients should not receive live virus vaccines. Lack of resolution of chylothorax can lead to inanition, infection, and death.

TREATMENT

Spontaneous recovery occurs in >50% of cases of neonatal chylothorax. Initial therapy includes enteral feedings with a low-fat or medium-chain triglyceride, high-protein diet or parenteral nutrition. Thoracentesis is repeated as needed to relieve pressure symptoms; tube thoracostomy is often performed. If there is no resolution in 1-2 wk, total parenteral nutrition is instituted; if this measure is unsuccessful, a pleuroperitoneal shunt, thoracic duct ligation, or application of fibrin glue is considered. Surgery should be considered earlier in neonates with massive chylothorax and chyle output of >50 mL/kg/day despite maximum medical therapy for 3 days. Parenteral octreotide at a dose of 0.5-1 μg/kg/hr to a maximum of 10 μg/kg/day intravenously has been used to manage chylothorax, but further study is needed. Other therapeutic approaches include percutaneous thoracic duct embolization, pressure control ventilation with positive end-expiratory pressure, talc or iodopovidone pleurodesis, and inhalation of nitric oxide. Treatment is similar for traumatic chylothorax. Chemical pleurodesis or irradiation is used in malignant chylothorax. OK432 (picibanil) has been used to treat fetal and newborn chylothorax.

Chapter 416

Bronchopulmonary Dysplasia

Steven O. Lestrud

Bronchopulmonary dysplasia (BPD) is a pathologic process leading to signs and symptoms of chronic lung disease that originates in the neonatal period (see Chapter 101). The pathogenesis of lung disease in the population of neonates weighing <1,000 g includes the contribution of immature development of airway and vascular structures of the lung. The currently accepted definition includes an oxygen requirement for 28 days postnatally, and the disorder is graded as mild, moderate, or severe on the basis of supplemental oxygen requirement and gestational age (Table 416-1).

CLINICAL MANIFESTATIONS

Physical findings of the pulmonary exam vary with the severity of disease. Tachypnea is a common finding. Mouth breathing because of narrowed nasal passages and high arched palate is noted on upper airway exam. The chest demonstrates an increased anteroposterior diameter that suggests air trapping. Intercostal retractions are frequently present. Although breath sounds are frequently clear when the patient is well and abnormal only during an acute exacerbation, many patients have baseline wheeze or coarse crackles. A persistent fixed wheeze or stridor suggests subglottic stenosis (see Chapter 388) or large airway malacia. Fine crackles may be present in patients prone to fluid overload.

The most severely affected patients require prolonged mechanical ventilation to achieve acceptable gas exchange. Supplemental oxygen may be required to maintain acceptable oxygen saturation and often is needed to minimize the work of breathing. Infants with significant lung disease exhibit growth failure from the elevated energy expenditure essential to maintain the increased metabolic demands of respiration. Chronic respiratory insufficiency may be evident as elevation of serum bicarbonate, elevation of pressure of carbon dioxide on blood gas analysis, or polycythemia.

Patients must be monitored for the development of cor pulmonale, especially if they require supplemental oxygen and have chronic respiratory insufficiency.

Table 416-1 Forms of Bronchopulmonary Dysplasia

FEATURES OF ALL BPD	ADDITIONAL FEATURES OF MILD BPD	ADDITIONAL FEATURES OF MODERATE BPD	ADDITIONAL FEATURES OF SEVERE BPD
<32 wk PMA Oxygen requirement 1st 28 days	Breathing room air at 36 wk PMA	<30% Supplemental oxygen at 36 wk PMA	>30% Supplemental oxygen at 36 wk PMA and mechanical support, CPAP, or ventilation
>32 wk PMA Oxygen requirement 1st 28 days of life	Breathing room air at 56 days of life	<30% Supplemental oxygen at 56 days of life	>30% Supplemental oxygen at 56 days of life and mechanical support, CPAP, or ventilation

BPD, bronchopulmonary dysplasia; CPAP, continuous positive airway pressure; PMA, postmenstrual age.

Gastroesophageal reflux disease (GERD) (see Chapter 323) and pulmonary aspiration complicate pulmonary status, particularly during an exacerbation when the infant is most tachypneic and when pulmonary mechanics increase the risk of GERD. Other conditions resulting from premature birth–complicating BPD include upper airway obstruction leading to hypoxia, neurodevelopmental delay with increased risk of aspiration, systemic hypertension with left ventricular hypertrophy, poor growth, and electrolyte disturbances.

In severely affected patients and patients with disease disproportionate to their risk for development of chronic lung disease, other pulmonary disease must be suspected, such as asthma (see Chapter 144), cystic fibrosis (see Chapter 403), and chronic aspiration pneumonitis (see Chapter 398). Recurrent episodes of respiratory distress are common, but anatomic airway abnormalities, such as subglottic stenosis (see Chapter 388) and airway malacia (see Chapter 386), must also be considered.

A **pulmonary exacerbation** of BPD is typically triggered during viral upper respiratory infections. Other frequent triggers include viral lower respiratory infections, sinusitis, otitis media, weather changes, exposure to cigarette smoke, and exacerbations of gastroesophageal reflux. During an exacerbation, the infant exhibits increased work of breathing, with tachypnea and retractions becoming more prominent. Chest wall configuration may change, with an increased anteroposterior diameter. If wheezing is a prominent baseline finding, poor air entry during an exacerbation may result in less wheezing, signifying a significant deterioration of respiratory status.

TREATMENT

Treatment is directed toward decreasing the work of breathing and normalizing gas exchange, to allow for optimal growth and neurodevelopment. Infants requiring supplemental oxygen past 35 wk postmenstrual age have a higher incidence of lower airway obstruction and bronchodilator responsiveness and are more likely to be hospitalized during the toddler years than their peers. The etiology of wheezing in BPD may be lower airway inflammation, bronchial smooth muscle irritation, bronchial smooth muscle hypertrophy, and airway malacia. The administration of an inhaled bronchodilator is frequently undertaken to evaluate an individual's response. Most commonly, inhaled β-agonists initially increase air movement and improve comfort of breathing, resulting in short-term improvement in pulmonary function values. For patients whose symptoms respond, the medication should be continued, especially during high-risk periods when triggers are present, such as an upper respiratory infection or hot humid days.

β-Agonists may worsen the air exchange, particularly in infants with BPD and concomitant airway malacia. Bronchial smooth muscle may maintain airway caliber in the affected airway; smooth muscle relaxation after administration of a β-agonist results in increased small airway collapse. Patients in whom β-agonists have these effects may benefit from alternative bronchodilators, such as inhaled ipratropium and oral methylxanthines. The administration of preventive anti-inflammatory medications, such as inhaled glucocorticoids and leukotriene-modifying agents, may be considered in patients with frequent inflammatory triggers.

Targeted goals for supplemental oxygen therapy after discharge from the nursery are to improve oxygen saturation values and decrease likelihood of desaturation, reduce the risk of cor pulmonale, diminish the work of breathing, and improve growth. This therapy likely improves neurodevelopmental outcome and may decrease exacerbations caused by hypoxia. Oxygen saturation values should exceed 90%, but the optimal goal above this level is unknown. The addition of diuretic therapy with furosemide or thiazides may improve pulmonary mechanics by decreasing lung water and allow tapering of supplemental oxygen. Therapy beyond several weeks, however, is not known to improve outcome and places the child at risk for electrolyte disorders.

Adequate caloric intake can be difficult for many reasons, including oral aversion, discoordinated suck and swallow, GERD, aspiration, and aspiration with GERD. In addition, tachypnea, episodic respiratory distress, increased work of breathing, and requirement for supplement oxygen place the infant at risk for growth failure. A high caloric intake is necessary, with ranges of 120-160 kcal/kg/day required, frequently in combination with fluid restriction. To provide such high caloric intake in the compromised infant, supplemental feedings through a nasogastric or gastrostomy tube may be considered. Careful attention is necessary to maintain fluid balance.

Gastroesophageal reflux is common and must be suspected in patients not showing response to therapy and in patients with frequent exacerbations, especially exacerbations without clear triggers. Definitive diagnosis is necessary because these patients will be subject to prolonged promotility and antacid medications. Appropriate antireflux therapy in infants with GERD decreases respiratory complications. Gastroesophageal reflux with pulmonary aspiration or aspiration alone may manifest as chronic chest congestion, wheezing, and episodic hypoxic spells. Fundoplication with a gastrostomy tube is performed in patients showing no response to medical therapy. Evaluation and treatment by a speech therapist, pediatric pulmonologist, or otolaryngologist may decrease the risk for development of chronic lung disease associated with aspiration.

Prevention of respiratory viral illness is vitally important; frequent handwashing by caregivers, especially before they handle the baby and avoidance of contact with children and adults with current respiratory symptoms are essential. Respiratory syncytial virus (see Chapter 260) immunoprophylaxis should be considered on the basis of the severity of lung disease, as well as the patient's gestational age and current age.

The prognosis for infants with BPD is generally good. Through school age, the family can expect frequent medical interactions for episodes of respiratory distress, commonly triggered by simple upper respiratory tract infections and weather changes. Pulmonary function in severely affected patients remains decreased, and exercise limitation may be present because of dyspnea. The most severely affected patients benefit from care administered by a multidisciplinary team of caregivers, including the pediatrician, pulmonologist, speech therapist, nutritionist, and developmental specialists.

Chapter 417

Skeletal Diseases Influencing Pulmonary Function

Steven R. Boas

Pulmonary function is influenced by the structure of the chest wall (see Chapter 373). Chest wall abnormalities can lead to restrictive or obstructive pulmonary disease, impaired respiratory muscle strength, and decreased ventilatory performance in response to physical stress. The congenital chest wall deformities include *pectus excavatum*, *pectus carinatum*, *sternal clefts*, *Poland syndrome*, and skeletal and *cartilage dysplasias*. Vertebral anomalies such as kyphoscoliosis can alter pulmonary function in children and adolescents.

417.1 Pectus Excavatum (Funnel Chest)

Steven R. Boas

ETIOLOGY

Pectus excavatum, midline narrowing of the thoracic cavity is usually an isolated skeletal abnormality. The cause is unknown. Pectus excavatum can occur in isolation or it may be associated with a connective tissue disorder (Marfan [see Chapter 702] or Ehlers-Danlos syndrome [see Chapter 659]). It may be acquired secondarily to chronic lung disease, neuromuscular disease, or trauma.

EPIDEMIOLOGY

Pectus excavatum occurs in 1 in 400 births with a 9 : 1 male preponderance and accounts for >90% of congenital chest wall anomalies. There is a positive family history in one-third of cases.

CLINICAL MANIFESTATIONS

The deformity is present at or shortly after birth in one-third of cases but is usually not associated with any symptoms at that time. In time, fatigue, chest pain, palpitations, recurrent respiratory infections, wheezing, stridor, and cough may be present. Decreased exercise tolerance is one of the most common symptoms. Because of the cosmetic nature of this deformity, children may experience significant psychologic stress. Physical examination may reveal sternal depression, protracted shoulders, kyphoscoliosis, dorsal lordosis, inferior rib flares, rib cage rigidity, forward head tilt, scapular winging, and loss of vertebral contours (Fig. 417-1). Patients exhibit paroxysmal sternal motion and a shift of point of maximal impulse to the left. Innocent systolic murmurs may be heard.

Figure 417-1 **Pectus excavatum in a 15 year old male.** Note the presence of protracted shoulders, inferior rib flares, and sternal depression.

LABORATORY FINDINGS

Lateral chest radiograms demonstrate the sternal depression. Use of the Haller index on chest CT (maximal internal transverse diameter of the chest divided by the minimal anteroposterior diameter at the same level) in comparison with age- and gender-appropriate normative values for determining the extent of depression of the chest wall anomaly has become useful in determining the extent of the anatomic abnormality. An electrocardiogram may show a right-axis deviation or Wolff-Parkinson-White syndrome (see Chapter 436); an echocardiogram may demonstrate mitral valve prolapse (see Chapter 428.3) and ventricular compression. Results of static pulmonary function tests may be normal but commonly show an obstructive defect in the lower airways and, less commonly, a restrictive defect as the result of abnormal chest wall mechanics. Exercise testing may demonstrate either normal tolerance or limitations from underlying cardiopulmonary dysfunction that are associated with the severity of the defect. Ventilatory limitations are commonly seen in younger children and adolescents, whereas cardiac limitations secondary to stroke volume impairments are more commonly seen in older adolescents and young adults.

TREATMENT

Treatment is based on the severity of the deformity and the extent of physiologic compromise as defined by physical examination and physiologic assessment of cardiopulmonary function (lung function and exercise tolerance assessment). Therapeutic options include careful observation, use of physical therapy to address musculoskeletal compromise, and corrective surgery. For patients with significant physiologic compromise, surgical correction may improve the cosmetic deformity and may help minimize or even improve the cardiopulmonary compromise. The 2 main surgical interventions are the Ravitch and Nuss procedures. Although superiority of 1 approach has not been established, there is now more than 20 yr of successful experience with the minimally invasive Nuss procedure. For teenagers with exercise limitations, surgical repair may result in improved exercise tolerance. Normalization of lung perfusion scans and maximal voluntary ventilation have also been observed after surgery. Utilization of a magnetic brace with gradual remodeling of the pectus deformity is under clinical investigation. Ongoing treatment to address the secondary musculoskeletal findings is commonly employed before and after the operation.

Bibliography is available at Expert Consult.

417.2 Pectus Carinatum and Sternal Clefts

Steven R. Boas

PECTUS CARINATUM

Etiology and Epidemiology

Pectus carinatum is a sternal deformity accounting for 5-15% of congenital chest wall anomalies. Anterior displacements of the mid and lower sternum and adjacent costal cartilages are the most common types. They are most commonly associated with protrusion of the upper sternum; depression of the lower sternum occurs in only 15% of patients. Asymmetry of the sternum is common, and localized depression of the lower anterolateral chest is also often observed. Males are affected 4 times more often than females. There is a high familial occurrence and a common association of mild to moderate scoliosis. Mitral valve disease and coarctation of the aorta are associated with this anomaly. Three types of anatomic deformity occur (upper, lower, and lateral pectus carinatum), with corresponding physiologic changes and treatment algorithms.

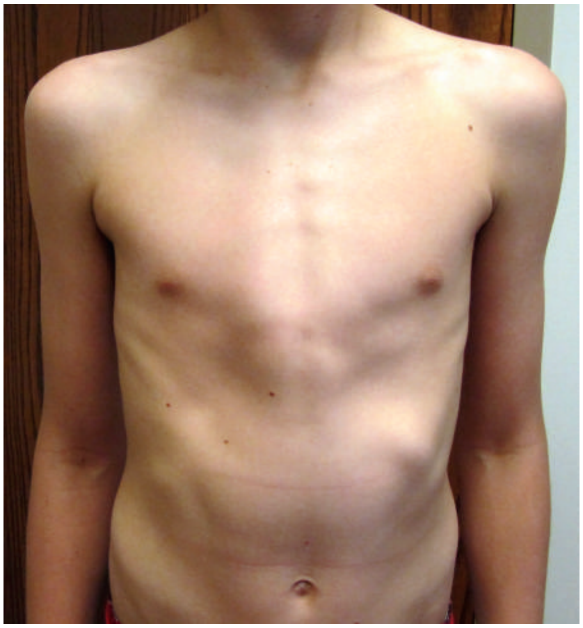

Figure 417-2 Pectus carinatum in a 13 year old male. Note the central sternal prominence.

Clinical Manifestations

In early childhood, symptoms appear minimal. School-age children and adolescents commonly complain of dyspnea with mild exertion, decreased endurance with exercise, and exercise-induced wheezing. The incidence of increased respiratory infections and use of asthma medication is higher than in nonaffected individuals. On physical examination, a marked increase in the anteroposterior chest diameter is seen, with resultant reduction in chest excursion and expansion (Fig. 417-2). Spirometry has demonstrated both restrictive and obstructive patterns, although the majority of individuals have normal values. Increases in residual volume are often present and results in tachypnea and diaphragmatic respirations. Exercise testing shows variable results. Chest radiographs show an increased anteroposterior diameter of the chest wall, emphysematous-appearing lungs, and a narrow cardiac shadow. The pectus severity score (width of chest divided by distance between sternum and spine; analogous to the Haller index) is reduced.

Treatment

For symptomatic patients with pectus carinatum, minimally invasive surgical correction procedures may result in improvement of the clinical symptoms. Many surgeons prefer to utilize bracing techniques as a first-line treatment although prospective outcome data is limited. Although surgery is performed for some individuals who are symptomatic, it is often performed for cosmetic and psychologic reasons.

STERNAL CLEFTS

Sternal clefts are rare congenital malformations that result from the failure of the fusion of the sternum during the 8th wk of gestation. No familial predisposition has been described. Sternal clefts occur in less than 1% of all chest wall deformities. Sternal clefts are classified as partial or complete. Partial sternal clefts are more common and may involve the superior sternum in association with other lesions, such as vascular dysplasias and supraumbilical raphe, or the inferior sternal clefts, which are often associated with other midline defects (pentalogy of Cantrell). Complete sternal clefts with complete failure of sternal fusion are rare. These disorders may also occur in isolation. The paradoxic movement of thoracic organs with respiration may alter pulmonary mechanics. Rarely, respiratory infections and even significant compromise result. Surgery is required early in life, before fixation and immobility occur.

Bibliography is available at Expert Consult.

417.3 Asphyxiating Thoracic Dystrophy (Thoracic-Pelvic-Phalangeal Dystrophy)

Steven R. Boas

ETIOLOGY

A multisystem autosomal recessive disorder, asphyxiating thoracic dystrophy results in a constricted and narrow rib cage. Also known as *Jeune syndrome*, the disorder is associated with a characteristic skeletal abnormalities as well as variable involvement of other systems, including renal, hepatic, neurologic, pancreatic, and retinal abnormalities (see Chapter 700).

CLINICAL MANIFESTATIONS

Most patients with this disorder die shortly after birth from respiratory failure, although less-aggressive forms have been reported in older children. For those who survive the neonatal period, progressive respiratory failure often ensues, owing to impaired lung growth, recurrent pneumonia, and atelectasis originating from the rigid chest wall.

DIAGNOSIS

Physical examination reveals a narrowed thorax that, at birth, is much smaller than the head circumference. The ribs are horizontal, and the child has short extremities. Chest radiographs demonstrate a bell-shaped chest cage with short, horizontal, flaring ribs and high clavicles.

TREATMENT

No specific treatment exists, although thoracoplasty to enlarge the chest wall and long-term mechanical ventilation has been tried. Rib-expanding procedures have resulted in improved survival.

PROGNOSIS

For some children with asphyxiating thoracic dystrophy, improvement in the bony abnormalities occurs with age. However, children younger than age 1 yr often succumb to respiratory infection and failure. Progressive renal disease often occurs with older children. Use of vaccines for influenza and other respiratory pathogens is warranted, as is aggressive use of antibiotics for respiratory infections.

Bibliography is available at Expert Consult.

417.4 Achondroplasia

Steven R. Boas

ETIOLOGY

Achondroplasia is the most common condition characterized by disproportionate short stature (see Chapter 696). This condition is inherited as an autosomal dominant disorder that results in disordered growth. Much has been learned about this disorder, including its genetic origins (95% of cases caused by mutations in the gene coding for fibroblast growth factor receptor type 3) and how to minimize its serious complications.

CLINICAL MANIFESTATIONS

Restrictive pulmonary disease, affecting <5% of children with achondroplasia who are younger than 3 yr, is more likely at high elevation. Recurrent infections, cor pulmonale, and dyspnea are commonly associated. There is an increased risk of obstructive sleep apnea or hypopneas. Hypoxemia during sleep is a common feature. Onset of restrictive lung disease can begin at a very young age. On examination, the breathing pattern is rapid and shallow, with associated abdominal breathing. The anteroposterior diameter of the thorax is reduced. Special growth curves for chest circumference of patients with achondroplasia from birth to 7 yr are available. Three distinct phenotypes exist: phenotypic group 1 patients possess relative adenotonsillar hypertrophy, group 2 patients have muscular upper airway obstruction and progressive hydrocephalus, and group 3 patients have upper airway obstruction without hydrocephalus. Kyphoscoliosis may develop during infancy.

DIAGNOSIS

Pulmonary function tests reveal a reduced vital capacity that is more pronounced in males. The lungs are small but functionally normal. Sleep studies are recommended due to the high prevalence of sleep-disordered breathing. Chest radiographs demonstrate the decreased anteroposterior diameter along with anterior cupping of the ribs. The degree of foramen magnum involvement correlates with the extent of respiratory dysfunction.

TREATMENT

Treatment of sleep apnea, if present, is supportive (see Chapter 19). Physiotherapy and bracing may minimize the complications of both kyphosis and severe lordosis. Aggressive treatment of respiratory infections and scoliosis is warranted.

PROGNOSIS

The life span is normal for most children with this condition, except for the phenotypic groups with hydrocephalus or with severe cervical or lumbar spinal compression.

417.5 Kyphoscoliosis: Adolescent Idiopathic Scoliosis and Congenital Scoliosis

Steven R. Boas

ETIOLOGY

Adolescent idiopathic scoliosis (AIS) is characterized by lateral bending of the spine (see Chapter 679). It commonly affects children during their teen years, as well as during periods of rapid growth. The cause is unknown. Congenital scoliosis is uncommon, affecting girls more than boys, and is apparent in the 1st yr of life (see Chapter 679.2).

CLINICAL MANIFESTATIONS

The pulmonary manifestations of scoliosis may include chest wall restriction, leading to a reduction in total lung capacity, abnormal gas exchange, and airway obstruction. The angle of scoliosis deformity has been correlated with the degree of lung impairment only for patients with thoracic curves. Vital capacity, forced expiratory volume in 1 sec (FEV_1), work capacity, oxygen consumption, diffusion capacity, chest wall compliance, and partial pressure of arterial oxygen decrease as the severity of thoracic curve increases. These findings can be seen in even mild to moderate AIS (Cobb angle <30 degrees) but generally do not occur in other, nonthoracic curves. Respiratory compromise is often more severe in children younger than 5 yr of age with large scoliotic curves. Reduction in peripheral muscle function is associated with AIS through either intrinsic mechanisms or deconditioning. Severe impairment can lead to cor pulmonale or respiratory failure and can occur before age 20 yr. Children with severe scoliosis, especially boys, may have abnormalities of breathing during sleep, and the resultant periods of hypoxemia may contribute to the eventual development of pulmonary hypertension.

DIAGNOSIS

Physical examination and an upright, posteroanterior radiograph with subsequent measurement of the angle of curvature (Cobb technique) remain the gold standard for assessment of scoliosis. Curves >10 degrees define the presence of scoliosis. Lung volume, respiratory muscle strength, and exercise capacity determination are essential in assessing the degree of respiratory compromise associated with scoliosis.

TREATMENT

Depending on the extent of the curve and the degree of skeletal maturation, treatment options include reassurance, observation, bracing, and surgery (spinal fusion). Influenza vaccine should be administered, given the extent of pulmonary compromise that may coexist. Because vital capacity is a strong predictor for the development of respiratory failure in untreated AIS, surgical goals are to diminish the scoliotic curve, maintain the correction, and prevent deterioration in pulmonary function. Abnormalities of vital capacity and total lung capacity, exercise intolerance, and the rate of change of these variables over time should be taken into consideration for the timing of surgical correction. Preoperative assessment of lung function (i.e., lung volumes, oxygen consumption, muscle strength, ventilation/perfusion) may assist in predicting postsurgical pulmonary difficulties. Many patients undergoing surgical correction may be managed postoperatively without mechanical ventilation. Even patients with mild scoliosis may have pulmonary compromise immediately after spinal fusion, secondary to pain and a body cast that may restrict breathing and interfere with coughing. Children with a preoperative FEV_1 <40% predicted are at risk for requiring prolonged postoperative mechanical ventilation. Rib-expanding procedures have been successful in severe cases of congenital scoliosis. Choice of surgical approach may also impact lung function postoperatively.

Bibliography is available at Expert Consult.

417.6 Congenital Rib Anomalies

Steven R. Boas

CLINICAL MANIFESTATIONS

Isolated defects of the highest and lowest ribs have minimal clinical pulmonary consequences. Missing midthoracic ribs are associated with the absence of the pectoralis muscle (Poland syndrome), and lung function can become compromised. Associated kyphoscoliosis and hemivertebrae may accompany this defect. If the rib defect is small, no significant sequelae ensue. When the 2nd to 5th ribs are absent anteriorly, lung herniation and significant abnormal respiration ensue. The lung is soft and nontender and may be easily reducible on examination. Complicating sequelae include severe lung restriction (secondary to scoliosis), cor pulmonale, and congestive heart failure. Symptoms are often minimal but can cause dyspnea. Respiratory distress is rare in infancy.

DIAGNOSIS

Chest radiographs demonstrate the deformation and absence of ribs with secondary scoliosis. Most rib abnormalities are discovered as incidental findings on a chest film.

TREATMENT

If symptoms are severe enough to cause clinical compromise or significant lung herniation, then homologous rib grafting can be performed. Rib-expanding procedures are also of great value. A modified Nuss procedure has been utilized to correct associated chest wall anomalies with rib abnormalities. Adolescent girls with congenital rib anomalies may require cosmetic breast surgery.

Chapter 418

Chronic Severe Respiratory Insufficiency

Zehava L. Noah and Cynthia Etzler Budek

The population of pediatric patients receiving long-term mechanical ventilatory support has increased in the United States and many other nations because of improvements in the treatment of acute respiratory failure and advancements in invasive (e.g., tracheostomy with mechanical ventilator) and noninvasive (e.g., mask continuous

positive airway pressure [CPAP] or bilevel positive airway pressure [BiPAP]) ventilation. Despite the growing population, less than 1% of patients admitted to pediatric intensive care units require long-term mechanical ventilation. Infants, children, and adolescents with disorders of central control of breathing, disease of the airways, residual lung disease after severe respiratory illness, persistent pulmonary hypertension, and neuromuscular disorders may experience hypercarbic and/or hypoxemic chronic respiratory failure. Generally, the respiratory failure can be attributed to a primary cause, although many children have multiple causative factors. **Chronic respiratory failure** can be defined as pulmonary insufficiency for a protracted period, usually 28 days or longer.

Patients are maintained on long-term ventilation for varying periods of time depending on the underlying pathology. Patients with reversible neuropathies (Guillain-Barré syndrome, neuropathy of critical illness), bronchopulmonary dysplasia, pulmonary hypertension, airway abnormalities, and congenital heart disease before or after surgical intervention require long-term ventilation as a bridge for full recovery. Patients with conditions such as central hypoventilation, progressive neuromuscular disease, and high quadriplegia may need ventilatory support indefinitely. The goals of long-term mechanical ventilation are to sustain and extend life, enhance the quality of life, reduce morbidity, improve physical and psychologic function, and enhance growth and development. These goals are often optimized in the home setting, which is the preferred site of discharge for children who are ventilator dependent. When social circumstances do not allow for a safe discharge to home, patients may be transferred to a highly skilled nursing facility for long-term care.

In an observational cohort analysis of 228 children enrolled in a home ventilation program 52% had chronic pulmonary disease, many with multiple comorbidities. Eventually 30% of children with chronic pulmonary disease were successfully weaned off ventilation and 19% died. Twenty-seven percent of the total population had neuromuscular disease, of which 6% were weaned off ventilation and 21% died. Twenty percent of the total population had central hypoventilation, of which 4% were weaned from ventilation and 24% died. Causes of death included progression of underlying chronic respiratory failure (34%), cardiac failure (21%), acute respiratory failure, tracheal bleeding and tracheal obstruction (8.5% each), and tracheostomy accident (2%). Regression analysis suggested that children with chronic pulmonary disease were more likely to successfully wean off mechanical ventilation than those children in the other two groups.

418.1 Neuromuscular Diseases

Zehava L. Noah and Cynthia Etzler Budek

Neuromuscular diseases (NMDs) of childhood include muscular dystrophies, metabolic and congenital myopathies, anterior horn cell disorders, peripheral neuropathies, and diseases that affect the neuromuscular junction. Decreased muscle strength and endurance resulting from neuromuscular disorders can affect any skeletal muscle, including muscles involved in respiratory function. Of particular concern are those muscles mediating upper airway patency, generation of cough, and lung inflation. Acute respiratory insufficiency is typically the most prominent clinical manifestation of several acute neuromuscular disorders, including high-level spinal cord injury, poliomyelitis, Guillain-Barré syndrome (see Chapter 616), and botulism (see Chapter 210). Respiratory dysfunction constitutes the leading cause of morbidity and mortality in progressive neuromuscular disorders (e.g., Duchenne muscular dystrophy [see Chapter 609], spinal muscular atrophy, congenital myotonic dystrophy, myasthenia gravis [see Chapter 612], and Charcot-Marie-Tooth disease [see Chapter 613]).

PATHOGENESIS

Early onset of NMD can lead to chest wall deformity and lung disease as a consequence of developmental factors. In infancy, the chest wall is very compliant with relatively stiff lungs and small airways. With progressive weakness of the intercostal muscles, the chest wall becomes even more compliant. Small airways have a tendency to become obstructed, leading to microatelectasis and decreased functional residual capacity. The compliant chest wall with initial sparing of diaphragm function leads to development of a small bell-shaped chest with depressed sternum, protruding abdomen, and paradoxical breathing, typically seen in spinal muscular atrophy (SMA) type 1. As the disease progresses, severe hypotonia develops, chest wall muscles shorten and lose elasticity, costosternal and costovertebral joints contract, and lung volumes decrease. Inspiratory and expiratory pressures subsequently decrease, expiratory pressures more so than inspiratory, causing ineffective cough and poor airway clearance. As the child with NMD ages, kyphoscoliosis commonly develops, increasing the severity of restrictive lung disease. Although central control of breathing remains normal, response to central chemoreceptors may decrease because of chronic hypercapnia.

TREATMENT

Even though gene-targeted therapies are being developed for some NMDs, current interventions are primarily supportive rather than curative. Close surveillance through periodic review of the history and physical examination is critical. The development of personality and behavioral changes, such as irritability, decreased attention span, fatigue, and somnolence, may point to the presence of sleep-associated gas exchange abnormalities and sleep fragmentation. Changes in speech and voice characteristics, nasal flaring, and the use of accessory muscles at rest may indicate progressive muscle dysfunction and respiratory compromise. Although the frequency of periodic reevaluation needs to be tailored to the individual child, guidelines were developed for the Duchenne muscular dystrophy population; an abbreviated summary of such recommendations, applicable to all children with NMDs, is provided in Table 418-1.

Guidelines for evaluation and management of patients with SMA were developed on the basis of expert consensus. Four classifications of SMA, based on age of onset and level of function, are recognized (Table 418-2). Treatment of SMA is focused on level of function (non-sitter, sitter, or walker) rather than SMA type. Unlike patients with Duchenne muscular dystrophy, patients with SMA do not demonstrate correlation between pulmonary function and need for mechanical

Table 418-1 Proposed Guidelines for Initial Evaluation and Follow-Up of Patients with Neuromuscular Disease

INITIAL EVALUATION	BASIC INTERVENTION/ TRAINING
History/physical/anthropometrics	Nutritional consultation and guidance
Lung function and maximal respiratory pressures (PFTs)	Regular chest physiotherapy
Arterial blood gases	Use of percussive devices
Polysomnography*	Respiratory muscle training
Exercise testing (in selected cases)	Annual influenza vaccine
If vital capacity >60% predicted or maximal respiratory pressures >60 cm H_2O	Evaluate PFTs every 6 mo CXR and polysomnography every year
If vital capacity <60% predicted or maximal respiratory pressures <60 cm H_2O	Evaluate PFTs every 3-4 mo CXR, MIP/MEP every 6 mo Polysomnography every 6 mo to year

*Please note that if polysomnography is not readily available, multichannel recordings including oronasal airflow, nocturnal oximetry, and end-tidal carbon dioxide levels may provide an adequate alternative.

CXR, chest x-ray; MEP, maximal expiratory pressure; MIP, maximal inspiratory pressure; PFT, pulmonary function test.

Table 418-2 Clinical Classification of Spinal Muscular Atrophy

SMA TYPE	AGE OF ONSET	HIGHEST FUNCTION	NATURAL AGE OF DEATH
Type 1 (severe)	0-6 mo	Never sits	<2 yr
Type 2 (intermediate)	7-18 mo	Never stands	<2 yr
Type 3 (mild)	Older than 18 mo	Stands and walks	Adult
Type 4 (adult)	Second or third decade	Walks during adult years	Adult

ventilatory support. Longitudinal monitoring for signs and symptoms of sleep-disordered breathing and ineffective airway clearance should be utilized to direct patient care.

Bibliography is available at Expert Consult.

418.2 Congenital Central Hypoventilation Syndrome

Zehava L. Noah, Cynthia Etzler Budek, and Debra E. Weese-Mayer

Congenital central hypoventilation syndrome (CCHS) is a clinically complex disorder of respiratory and autonomic regulation. In the classic case of CCHS, symptoms of alveolar hypoventilation are manifest in the newborn period and during sleep only—with diminished tidal volume and a typically monotonous respiratory rate with cyanosis and hypercarbia. In more severe cases of CCHS, the hypoventilation is manifest during wakefulness and sleep. And in the cases of later-onset CCHS (LO-CCHS), symptoms are manifest after 1 mo of age (and often into childhood and adulthood) but hypoventilation is typically during sleep only. CCHS and LO-CCHS are further characterized by ventilatory failure to properly respond to hypercarbia and hypoxemia during wakefulness and sleep coupled with physiologic and/or anatomic autonomic nervous system (ANS) dysregulation (ANSD). Physiologic ANSD may include all organ systems affected by the ANS, specifically the respiratory, cardiac (sinus node pauses, asystole), sudomotor, vasomotor, ophthalmologic, neurologic, and enteric systems. The anatomic or structural ANSD includes Hirschsprung disease and tumors of neural crest origin (neuroblastoma, ganglioneuroma, or ganglioneuroblastoma). Diagnosis and management of individuals with CCHS and LO-CCHS have improved considerably, owing to greater knowledge in genetic testing, comprehensive care, and availability of monitoring technology for the home.

GENETICS

Mutations in the paired-like homeobox 2B (*PHOX2B*) gene are the cause of CCHS. *PHOX2B* is essential to the embryologic development of the ANS from the neural crest, and is expressed in key regions that explain much of the CCHS phenotype. Individuals with CCHS are heterozygous for either a polyalanine repeat expansion mutation (PARM) in exon 3 of the *PHOX2B* gene (normal number of alanines is 20 with normal genotype 20/20), such that individuals with CCHS have 24-33 alanines on the affected allele (genotype range is 20/24-20/33), or a non–PARM (NPARM) resulting from a missense, nonsense, frameshift, or stop codon mutation. Roughly 90-92% of the cases of CCHS have PARMs and the remaining 8-10% of cases have NPARMs. LO-CCHS cases have consistently had the 20/24 or 20/25 genotypes, or, occasionally, a very small NPARM. The specific type of *PHOX2B* mutation is clinically significant as it can help with anticipatory guidance in patient management. Less than 1% of CCHS cases will have a deletion of most of exon 3 or the entire *PHOX2B* gene, although the specific phenotype related to these large deletion mutations is not entirely clear. Stepwise clinical *PHOX2B* testing for probands with the CCHS phenotype is advised (step 1: fragment analysis (screening test); then if negative, step 2: sequel sequencing; then if negative, step 3: muliplex ligation-dependent probe amplification) to minimize expense and expedite confirmation of the diagnosis.

The majority of CCHS cases occur because of a de novo *PHOX2B* mutation, but up to 25% of children with CCHS inherit the mutation in an autosomal dominant manner from a seemingly asymptomatic parent who is mosaic for the *PHOX2B* mutation. Therefore, an individual with CCHS has a 50% chance of transmitting the mutation and resulting disease phenotype, to each offspring. Mosaic parents have up to a 50% chance of transmitting the *PHOX2B* mutation to each successive offspring. Genetic counseling is essential for family planning and for delivery room preparedness in anticipation of a CCHS birth. *PHOX2B* testing is advised for both parents of a child with CCHS to anticipate risk of recurrence in subsequent pregnancies and to determine if a parent has yet undiagnosed LO-CCHS. However, only fragment analysis *PHOX2B* testing (also known as the screening test) will identify low level somatic mosaicism (it will be missed by sequencing testing). At present, no clinical testing is available to determine germline mosaicism, but prenatal testing for *PHOX2B* mutation is clinically available (http://www.genetests.org) for families with a known *PHOX2B* mutation.

Ventilator Dependence

A correlation between the *PHOX2B* genotype and ventilator dependence is reported. The greater the number of extra alanines, the more likely the need for continuous ventilatory support, at least among the most common *PHOX2B* PARM genotypes (20/25, 20/26, 20/27). Thus patients with the 20/25 genotype seldom require awake ventilatory support, although they do require support during sleep. Patients with the 20/26 genotype have variable awake support needs, and patients with the 20/27 genotype and those with NPARMs are likely to need continuous ventilatory support.

Hirschsprung Disease

See Chapter 332.3.

Overall, 20% of children with CCHS also have Hirschsprung disease, and any infant or child with CCHS or LO-CCHS who presents with constipation should undergo rectal biopsy to screen for absence of ganglion cells. The type of *PHOX2B* mutation can help the primary physician anticipate which individuals are at higher risk. The frequency of Hirschsprung disease seems to increase with the longer polyalanine tracts (genotypes 20/27-20/33) and in those with NPARMs. Thus far only 1 infant with the 20/25 genotype has been reported to have Hirschsprung disease.

Tumors of Neural Crest Origin

Tumors of neural crest origin are more frequent in patients with NPARMs (50%) than in those with PARMs (1%). These extracranial tumors are more often neuroblastomas in individuals with NPARMs, rather than ganglioneuromas and ganglioneuroblastomas, which have been described in patients with longer PARMs (20/29, 20/30, and 20/33 genotype only). Thus far only 1 infant with a PARM (20/33 genotype) has been reported to have a neuroblastoma.

Cardiac Asystole

Transient, abrupt, and prolonged sinus pauses have been identified in patients with CCHS, necessitating implantation of cardiac pacemakers when the pauses are 3 sec or longer. Among patients with the *PHOX2B*

genotypes, 19% of those with the 20/26 genotype and 83% of those with the 20/27 genotype have heart beat pauses of 3 sec or longer. Children with the 20/25 genotype are not noted to have prolonged asystole, although 2 adults diagnosed with LO-CCHS demonstrated prolonged asystoles of 4-8 sec duration. Risk for sinus pauses among children with NPARMs is unknown at present.

Autonomic Nervous System Dysregulation

A higher number of polyalanine repeats among the PARMs is associated with an increased number of physiologic symptoms of ANSD. A higher frequency of anatomic ANSD findings is seen in individuals with CCHS who have NPARMs than in those who have PARMs. In addition, there is a spectrum of physiologic ANSD symptoms, including decreased heart rate variability, esophageal/gastric/colonic dysmotility, decreased pupillary response to light, reduced basal body temperature, altered distribution and amount of diaphoresis, and altered perception of anxiety.

Facial Phenotype

Children with CCHS and PARMs have a characteristic facies that is boxy in appearance, flattened on profile, and short relative to its width. The following five variables correctly predict 86% of CCHS cases: upper lip height, binocular width, upper facial height, nasal tip protrusion, and inferior inflection of the lateral one-third of the upper lip vermillion border (lip trait).

Neuropathology

Anatomic findings in the brains of individuals with CCHS from early MRI studies were unremarkable, and those from autopsies were inconsistent before 2003 when *PHOX2B* testing became clinically available. In a small cohort of adolescents with suspected CCHS, although without consistent *PHOX2B* mutation confirmation, neuropathologic brainstem changes were identified by diffusion tensor imaging in structures known to mediate central chemosensitivity and to link a network of cardiovascular, respiratory, and affective responses. The neuroanatomic defects in CCHS are likely the result of focal *PHOX2B* (mis) expression coupled with sequelae of recurrent hypoxemia/hypercarbia in the subset of suboptimally managed patients. On the basis of rodent studies and functional MRI in humans, the following regions pertinent to respiratory control show *PHOX2B* expression in the pons and medulla of the brainstem: locus coeruleus, dorsal respiratory group, nucleus ambiguus, parafacial respiratory group, among other areas. Physiologic evidence suggests that the respiratory failure in these children is mostly based on defects in central mechanisms, but peripheral mechanisms (mainly carotid bodies) may also be important.

Patients with CCHS have deficient carbon dioxide sensitivity during wakefulness and sleep such that they do not respond with a normal increase in ventilation in either state nor do they arouse in response to hypercarbia and/or hypoxemia during sleep. During wakefulness, a subset of patients may respond sufficiently to avoid significant hypercarbia, but most individuals with CCHS have hypoventilation that is severe enough that hypercarbia is apparent in the resting awake state. Children with CCHS also have altered sensitivity to hypoxia while awake and asleep. A key feature of CCHS is the lack of respiratory distress or sense of asphyxia with physiologic compromise (hypercarbia and/or hypoxemia). This lack of responsiveness to hypercarbia and/or hypoxemia with subsequent respiratory failure does not seem to consistently improve with age. A subset of older children with CCHS may show an increase in ventilation (specifically increase in respiratory rate rather than increase in tidal volume) when they are exercised at various work rates, a response that is possibly secondary to neural reflexes from rhythmic limb movements—although the increase in minute ventilation is often insufficient to avoid physiologic compromise.

CLINICAL MANIFESTATIONS

Patients with CCHS usually present in the 1st few hr after birth. Most children are the products of uneventful pregnancies and are term infants with appropriate weight for gestational age; Apgar scores have been variable. The affected infants do not show signs of respiratory distress, but their shallow respirations and respiratory pauses (apnea) evolve to respiratory failure with apparent cyanosis in the 1st day of life. In neonates with CCHS, the $Paco_2$ accumulates during sleep to very high levels, sometimes >90 mm Hg, and may decline to normal levels after the infants awaken. This problem becomes most apparent with failure of multiple attempts at extubation in an intubated neonate (who appears well with ventilatory support but in whom respiratory failure develops after removal of the support). However, the more severely affected infants hypoventilate awake and asleep; thus the previously described difference in $Paco_2$ between states is not apparent. Often, the respiratory rate is higher in rapid eye movement sleep than in nonrapid eye movement sleep in individuals with CCHS.

LO-CCHS should be suspected in infants, children, and adults who have unexplained hypoventilation, especially subsequent to the use of anesthetic agents, sedation, acute respiratory illness, and potentially treated obstructive sleep apnea. These individuals may have other evidence of chronic hypoventilation, including pulmonary hypertension, polycythemia, elevated bicarbonate concentration, difficulty concentrating, and mild unexplained neurocognitive impairment.

Besides treatment for the alveolar hypoventilation, children with CCHS require comprehensive physiologic evaluation and coordinated care to optimally manage associated abnormalities such as Hirschsprung disease, tumors of neural crest origin, symptoms of physiologic ANSD including cardiac asystole, among other findings (details provided in American Thoracic Society 2010 Statement on CCHS).

DIFFERENTIAL DIAGNOSIS

Testing should be performed to rule out primary neuromuscular, lung, and cardiac disease as well as an identifiable brainstem lesion that could account for the full constellation of symptoms characteristic of CCHS. Introduction of clinically available *PHOX2B* genetic testing allows for early and definitive diagnosis of CCHS. Because CCHS mimics many treatable and/or genetic diseases, the following disorders should be considered: X-linked myotubular myopathy, multiminicore disease, congenital myasthenic syndrome, altered airway or intrathoracic anatomy (diagnosis made with bronchoscopy and chest CT), diaphragm dysfunction (diagnosis made with diaphragm fluoroscopy), congenital cardiac disease, a structural hindbrain or brainstem abnormality (diagnosis made with MRI of the brain and brainstem), Möbius syndrome (diagnosis made with MRI of the brain and brainstem and neurologic examination), and specific metabolic diseases, such as Leigh syndrome, pyruvate dehydrogenase deficiency, and discrete carnitine deficiency. However the profound hypercarbia without respiratory distress during sleep will quickly lead the clinician to consider the diagnosis of CCHS or LO-CCHS.

Rapid-Onset Obesity with Hypothalamic Dysfunction, Hypoventilation, and Autonomic Dysregulation

Previously referred to as LO-CHS with hypothalamic dysfunction, **ROHHAD** (rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation) is a very rare disorder that was renamed to clarify that it is distinct from LO-CCHS (Chapter 47). The acronym describes the general sequence or "unfolding" of presenting symptoms, which can evolve over several years. The most dramatic and sentinel feature of ROHHAD is the rapid-onset weight gain (often >20 lb), which occurs over a 6-12 mo period in a seemingly normal young child. The diagnosis is based on clinical criteria that include onset of obesity and alveolar hypoventilation after the age of 1.5 yr (typically between 2 and 7 yr of age) and evidence of hypothalamic dysfunction as defined by 1 or more of the following findings: rapid-onset obesity, hyperprolactinemia, central hypothyroidism, disordered water balance, failure of response to growth hormone stimulation, corticotropin deficiency, and delayed/precocious puberty. Although it may not be apparent early in the course, all children with ROHHAD will develop hypoventilation. Considering the high prevalence of cardiorespiratory arrest and multisystem involvement, children with this disorder require coordinated comprehensive care with attention to development of hypoventilation (such as with repeated

physiologic recordings awake and asleep), initiation of supported ventilation, bradycardia (via Holter monitor), treatment of hypothalamic dysfunction (with involvement of an pediatric endocrinologist), tumors of neural crest origin (often ganglioneuromas or ganglioneuroblastomas; with involvement of an oncologist), and behavioral/intellectual decline (with annual neurocognitive testing and aggressive educational intervention). With meticulous management of the airway, breathing, and circulation, children with ROHHAD seem to stabilize and begin improvement in awake spontaneous breathing—though longitudinal studies are in a preliminary stage at present. Because of the high incidence of neural crest tumors, ROHHAD may be a paraneoplastic disorder.

Children with ROHHAD may present with **obstructive sleep apnea (OSA)** after development of obesity, but ROHHAD is distinct from **OSA hypoventilation syndrome** and **obesity hypoventilation syndrome**. The child with ROHHAD will go onto to severe hypoventilation despite intervention for the OSA. In children with exogenous obesity, the existence of obesity hypoventilation syndrome is controversial and is often referred to as OSA hypoventilation syndrome because it describes chronic OSA with resulting overnight hypercarbia, hypoxemia, and frequent arousals that lead to an altered set point of the central control of breathing (insensitivity to hypercarbia), awake hypoventilation, and daytime sleepiness. In children with OSA hypoventilation syndrome, treatment of the upper airway obstruction would be expected to result in complete resolution of hypoventilation and daytime sleepiness. In contrast, among children with ROHHAD the relief of upper airway obstruction unveils the central alveolar hypoventilation that requires lifelong ventilatory support. Both are distinguished from LO-CCHS by the absence of a CCHS-related *PHOX2B* mutation and the presence of (often morbid) obesity.

MANAGEMENT

Supported Ventilation—Diaphragm Pacing

Depending on the severity of respiratory control deficit, the individual with CCHS can have various means of artificial ventilation: noninvasive positive pressure ventilation or mechanical ventilation via tracheostomy (see Chapter 418.4). Diaphragm pacing offers another mode of supported ventilation; it involves bilateral surgical implantation of electrodes beneath the phrenic nerves, with connecting wires to subcutaneously implanted receivers. The external transmitter, which is much smaller and lighter in weight than a ventilator, sends a signal to flat donut-shaped antennae that are placed on the skin, over the subcutaneously implanted receivers. A signal travels from the external transmitter, ultimately, to the phrenic nerve to stimulate contraction of the diaphragm. A tracheostomy is typically required, at least initially, because the pacers induce a negative pressure on inspiration as a result of the contraction of the diaphragm being unopposed by pharyngeal dilation. Individuals with CCHS who are ventilator-dependent 24 hr/day are ideal candidates for diaphragm pacing to provide increased ambulatory freedom (without the "ventilator tether") while they are awake; however, they still require mechanical ventilator support while they are asleep. This balance between awake pacing and asleep mechanical ventilation allows for a rest from phrenic nerve stimulation at night. A growing number of children and adults who require artificial ventilatory support during sleep only are now using diaphragm pacing, a more acceptable option since the introduction of thoracoscopic diaphragm pacer implantation and shortened recovery time postoperatively.

Monitoring in the Home

Home monitoring for individuals with CCHS and LO-CCHS is distinctly different from and more conservative than that for other children requiring long-term ventilation because those with CCHS lack innate ventilatory and arousal responses to hypoxemia and hypercarbia. In the event of physiologic compromise, other children are more likely to show clinical signs of respiratory distress. For children and adults with CCHS and LO-CCHS, the only means of determining adequate ventilation and oxygenation is with objective measures from a pulse oximeter, end-tidal carbon dioxide monitor, and close supervision of these values by a trained registered nurse in the home and at school. At a minimum, it is essential that individuals with CCHS have continuous monitoring with pulse oximetry and end-tidal carbon dioxide with registered nurse supervision during all sleep time. Ideally, this such monitoring should be present 24 hr per day because, even while awake, they are not able to sense or adequately respond to a respiratory challenge as may occur with ensuing respiratory illness, increased activity, or even the simple activity of eating. These recommendations apply to all CCHS and LO-CCHS patients regardless of the nature of their artificial ventilatory support—but especially those with diaphragm pacers as they have no intrinsic alarms in the diaphragm pacer device.

Bibliography is available at Expert Consult.

418.3 Other Conditions

Zehava L. Noah and Cynthia Etzler Budek

MYELOMENINGOCELE WITH ARNOLD-CHIARI TYPE II MALFORMATION

Arnold-Chiari type II malformation (see Chapter 591.11) is associated with myelomeningocele, hydrocephalus, and herniation of the cerebellar tonsils, caudal brainstem, and the fourth ventricle through the foramen magnum. Sleep-disordered breathing, including OSA and hypoventilation, has been reported. Direct pressure on the respiratory centers or brainstem nuclei, or increased intracranial pressure because of the hydrocephalus may be responsible. Vocal cord paralysis, apnea, hypoventilation, and bradyarrhythmias have also been reported. Patients with Arnold-Chiari type II malformation have blunted responses to hypercapnia, and to a lesser degree, hypoxia.

Management

An acute change in the ventilatory state of a patient with this malformation requires immediate evaluation. Consideration must be given to posterior fossa decompression and/or treatment of the hydrocephalus. If this treatment is unsuccessful in resolving central hypoventilation or apnea, tracheostomy and long-term mechanical ventilation should be considered.

RAPID-ONSET OBESITY, HYPOTHALAMIC DYSFUNCTION, AND AUTONOMIC DYSREGULATION

See Chapter 418.2.

Obesity Hypoventilation Syndrome

As its name implies, obesity hypoventilation syndrome is a syndrome of central hypoventilation during wakefulness in obese patients with sleep-disordered breathing. Although it was initially described mainly in adult obese patients, obese children have also demonstrated the syndrome. Sleep-disordered breathing is a combination of OSA, hypopnea, and/or sleep hypoventilation syndrome. Patients are hypercapnic with cognitive impairment, morning headache, and hypersomnolence during the day. Chronic hypoxemia may lead to pulmonary hypertension and cor pulmonale.

Obesity is associated with reduced respiratory system compliance, increased airway resistance, reduced functional residual capacity, and increased work of breathing. Affected patients are unable to increase their respiratory drive in response to hypercapnia. Leptin may have a role in this syndrome. The sleep-disordered breathing leads to compensatory metabolic alkalosis. Because of the long half-life of bicarbonate, its elevation causes compensatory respiratory acidosis during wakefulness with elevated $Paco_2$.

Management

The use of **CPAP** during sleep may be sufficient for many patients. Patients with hypoxemia may require **BiPAP** and supplemental oxygen. Tracheostomy may be considered for patients who do not tolerate mask ventilation.

ACQUIRED ALVEOLAR HYPOVENTILATION

Traumatic, ischemic, and inflammatory injuries to the brainstem, brainstem infarction, brain tumors, bulbar polio, and viral paraneoplastic encephalitis may also result in central hypoventilation.

OBSTRUCTIVE SLEEP APNEA

Epidemiology

Habitual snoring during sleep is extremely common during childhood. As many as 27% of children who snore are affected by **OSA.** The current obesity epidemic has affected the epidemiology of this condition. Peak prevalence is at 2-8 yr of age. The ratio between habitual snoring and OSA is 4 : 1 to 6 : 1.

Pathophysiology

OSA occurs when the luminal cross-sectional area of the upper airway is significantly reduced during inspiration. With increased airway resistance and reduced activation of pharyngeal dilators, negative pressure leads to upper airway collapse. The site of upper airway closure in children with OSA is at the level of tonsils and adenoids. The size of tonsils and adenoids increases throughout childhood up to 12 yr of age. Environmental irritants such as cigarette smoke or allergic rhinitis may accelerate the process. Reports now suggest that early viral infections may affect adenotonsillar proliferation.

Clinical Presentation

Snoring during sleep, behavioral disturbances, learning difficulties, excessive daytime sleepiness, metabolic issues, and cardiovascular morbidity may alert the parent or physician to the presence of OSA. Diagnosis is made with the help of airway radiograms and a polysomnogram.

Treatment

When adenotonsillar hypertrophy is suspected, a consultation with an ear, nose, and throat specialist for adenoidectomy and/or tonsillectomy may be indicated. For patients who are not candidates for surgical intervention or persist with OSA despite adenoidectomy and/or tonsillectomy, CPAP or BiPAP during sleep may alleviate the obstruction (see Chapter 19).

SPINAL CORD INJURY

Epidemiology

There are an estimated 11,000 new spinal cord injuries **(SCIs)** annually in the United States, with more than 50% resulting in quadriplegia. SCI is relatively rare in pediatric patients, with an incidence of 1-13% of all SCI patients. The incidence in infancy and early childhood is similar for boys and girls. The preponderance of SCI in adolescents is in males. Motor vehicle accidents, falls, sports injuries, and assaults are the main causes. SCI usually leads to lifelong disability.

Pathophysiology

Children with SCI have a disproportionately higher involvement of the upper cervical spine, high frequency of spinal cord injury without radiographic abnormality, delayed onset of neurologic deficits, and higher proportion of complete injury. Thus, there is a high likelihood in pediatric SCI of quadriplegia with intercostal muscle and/or diaphragmatic paralysis leading to respiratory failure.

Management

Immobilization and stabilization of the spine must be accomplished simultaneously with initial patient resuscitation. Children with high SCI typically require lifelong ventilation, so the decision to place a tracheostomy for chronic ventilatory support is usually made early in their course of treatment. Depending on the child's age and general condition, diaphragmatic pacing may be considered. Often patients with diaphragmatic pacing need tracheostomy placement if there is dyscoordination between pacing and glottal opening. Muscle spasms occur frequently in the SCI patient and are treated with muscle relaxants. Occasionally the muscle spasms involve the chest and present a serious impediment to ventilation. Continuous intrathecal infusion of muscle relaxant via an implanted subcutaneous pump may be indicated (see Chapter 606.5).

METABOLIC DISEASE

Mucopolysaccharidoses

See Chapter 88.

Mucopolysaccharidoses are a group of progressive hereditary disorders that lack the lysosomal enzymes that degrade glycosaminoglycans. Incompletely catabolized mucopolysaccharides accumulate in connective tissue throughout the body. The inheritance is autosomal recessive except for Hunt syndrome, which is X-linked. The diagnosis is suggested by the presence of glycosaminuria and is confirmed by a lysosomal enzyme assay. I-cell disease mucolipidosis type II is an inherited lysosomal disorder with accumulation of mucolipids. Phenotypically, it is similar to mucopolysaccharidoses, but the age of onset is earlier and there is no mucopolysacchariduria. Mucopolysaccharide deposits are frequently found in the head and neck and cause airway obstruction. Typically, the affected child has a coarse face and large tongue. Significant deposits are found in the adenoids, tonsils, and cartilage. Airway radiograms and a polysomnogram may help define the severity of the upper airway obstruction.

Treatment options have included enzyme replacement therapy and stem cell transplantation with limited success. Adenoidectomy and/or tonsillectomy may be indicated but surgery alone seldom solves the problem of airway obstruction. Noninvasive CPAP or BiPAP, or tracheostomy with ventilatory support may be helpful

Dysplasias

Campomelic dysplasia (see Chapter 698) and thanatophoric dysplasia (see Chapter 696) affect rib cage size, shape, and compliance, leading to respiratory failure. Most patients with these disorders do not survive beyond early infancy. Tracheostomy and ventilation may prolong life.

Glycogenosis Type Ii

See Chapter 87.1.

Glycogenosis type II is an autosomal recessive disorder. Clinical manifestations include cardiomyopathy and generalized muscle weakness. Cardiac issues may include heart failure and arrhythmias. Muscle weakness leads to respiratory insufficiency and sleep-disordered breathing. Treatment includes emerging therapies such as enzyme replacement therapy, chaperone molecules, and gene therapy. Supportive therapy may consist of either noninvasive ventilation, or tracheostomy and mechanical ventilation. Cardiac medications, protein-rich nutrition, and judicious physical therapy are additional measures that can be utilized.

Severe Tracheomalacia and/or Bronchomalacia (Airway Malacia)

Conditions associated with airway malacia include tracheoesophageal fistula, innominate artery compression, and pulmonary artery sling after surgical repair (see Chapter 389). Patients with tracheobronchomalacia present with cough, lower airway obstruction, and wheezing. Diagnosis is made via bronchoscopy, preferably with the patient breathing spontaneously in order to evaluate dynamic airway function. Positive end-expiratory pressure titration during the bronchoscopy helps identify the ideal airway pressure required to maintain airway patency and prevent tracheobronchial collapse.

Neuropathy of Severe Illness

Children recuperating from severe illness in the intensive care unit often have neuromuscular weakness from suboptimal nutrition. This neuromuscular weakness can be devastating when coupled with the catabolic effects of severe illness and the residual effects of sedatives, analgesics, and muscle relaxants, particularly if corticosteroids were administered. Children with neuromuscular compromise have limited ability to increase ventilation and usually do so by increasing respiratory rate. Because of weakness, costal and sternal retractions may not be observed. Children with severe neuromyopathy may respond to increased respiratory load by becoming apneic. A look of panic, a

change in vital signs such as significant tachycardia or bradycardia, and cyanosis may be the only signs of impending respiratory failure.

HEMATOLOGIC STEM-CELL TRANSPLANTATION

Hematologic stem cell transplant (HSCT) is a life-saving therapy for patients with hematologic, oncologic, and immunologic conditions. Historically, outcomes for these patients have been poor. Lung dysfunction after HSCT is a serious and often fatal complication. Common causes of HSCT lung dysfunction include bacterial, viral, and/or fungal infections, posttransplant lymphoproliferative disorder, idiopathic pneumonia syndrome, diffuse alveolar hemorrhage, pulmonary cytolytic thrombi, engraftment syndrome, and bronchiolitis obliterans. Improvements in the management of HSCT have resulted in decreased graft-versus-host disease severity. Improved critical care practices, such as more in-depth diagnostic evaluation and lung-sparing ventilator strategies, have resulted in improved outcomes. Despite improved outcomes, a subset of HSCT patients will require chronic respiratory support for prolonged periods of time. In addition to post HSCT therapy, ongoing care may include noninvasive or invasive home ventilation, tracheostomy placement, diuretics, and supplemental nutrition.

MITOCHONDRIAL DISEASES

See Chapter 86.

Mitochondria are primarily responsible for the production of adenosine triphosphate. Mitochondrial diseases are a heterogeneous group of diseases in which adenosine triphosphate production is disrupted. Mitochondrial diseases are increasingly recognized and diagnosed in the pediatric population. Organs with high-energy requirements such as the neurons, and skeletal and cardiac muscles are particularly vulnerable. Although myopathy is the most frequently recognized presentation of mitochondrial disease, it is often part of a multisystem disease process. Neurologic complications include progressive proximal myopathy, kyphoscoliosis, dyskinesia, dystonia and spasticity, stroke, epilepsy, and visual and hearing impairment. Nonneurologic manifestations include cardiomyopathy, gastrointestinal dysmotility, gastroesophageal reflux, delayed gastric emptying, and pseudoobstruction.

Respiratory complications of mitochondrial disease are multifactorial. Muscle weakness, kyphoscoliosis, muscle spasms, and movement disorders may result in a restrictive pattern, and respiratory compromise. Additionally, dyscoordinated swallow and reflux may result in aspiration. In some mitochondrial diseases such as Leigh syndrome (see Chapter 86), central hypoventilation is an integral part of the disease. Supportive care for these patients may include noninvasive or invasive ventilation, tracheostomy placement, diuretics, appropriate nutrition, and dietary supplements.

Bibliography is available at Expert Consult.

418.4 Long-Term Mechanical Ventilation

Zehava L. Noah and Cynthia Etzler Budek

Many children with chronic severe respiratory insufficiency will benefit from long-term ventilatory support. The goals of chronic ventilation are to maintain normal oxygenation and ventilation, and to minimize the work of breathing. Caring for a child on long-term ventilatory support in the home is a complex, physically demanding, emotionally taxing, and expensive process for the family. It changes the family routines, priorities, and overall lifestyle, and may adversely affect intrafamilial and extrafamilial relationships. The discharge process for a child likely to require long-term ventilatory support should start early in the hospitalization, before the child is medically stable and prior to transition to a portable ventilator that can be maintained in the home.

The child's disease prognosis is a critical factor to consider when deciding to initiate long-term ventilation. Children with degenerative neuromuscular disease, such as SMA type I, suffer from respiratory failure very early in life, often triggered by the first respiratory illness. Although some parents of children with SMA decide to provide only palliative end-of-life care (see Chapter 43), others choose long-term invasive or noninvasive ventilatory support. Young children with chronic lung disease and airway malacia have the potential to improve their pulmonary function and to wean successfully off the ventilator if provided with adequate ventilation, good nutrition, and measures to promote development and prevent further lung injury.

Successful home discharge depends on whether there are adequate resources in the community to support the family. Some hospital programs that transition children home on ventilators utilize professional nurses in the home to assist with round-the-clock care. This level of care depends on adequate funding as well as availability of nursing agencies with skilled nurses. Housing can be a significant barrier to discharge if the home lacks adequate space for the child and caretakers, equipment, and supplies, presents environmental safety issues, including building and electrical code violations, and/or requires extensive home modifications for mobility, including ramping and lifts.

Funding for home care is typically a challenge for this pediatric population. Even if they have private insurance, coverage for home care benefits is often very limited. In the United States, most states have public aid funds available to support the special needs of eligible children who are ventilator dependent, although the extent of coverage varies considerably across the country.

RESPIRATORY EQUIPMENT FOR HOME CARE

Modes of mechanical ventilation support are discussed in Chapter 71.1.

Noninvasive Equipment

Supplemental oxygen and positive pressure support can be administered by nasal cannula. The nasal cannula system has the ability to deliver heated, supersaturated, high-flow gases. There are a number of mechanical devices available for the delivery of CPAP and BiPAP. These devices attach to nasal and full-face masks or nasal pillows and are best suited for the treatment of OSA where ventilatory support is required for only a portion of the day, typically during sleep. Long-term use of mask ventilation in small children may result in mid-face dysplasia or pressure wounds. This type of ventilation has also been used in children with mild forms of respiratory insufficiency due to recurrent atelectasis and/or nocturnal hypoventilation, as well as for palliation in more severely affected patients.

Rocker Bed

A rocker bed moves in a longitudinal seesaw motion at a set cycle rate. The child is secured to the bed with a strap across the body. Movement of the bed and gravitational pull promotes diaphragm movement. The rocker bed may be an option for children with mild neuromuscular weakness such as children recuperating from Guillain-Barré syndrome. For safety reasons this device should not be placed in a home with toddlers or young children, who may get trapped in its rotating mechanism.

Cuirasse

The cuirasse is a negative-pressure device that resembles a hard turtle shell. It is a fiberglass piece that is custom fit over the child's anterior chest and provides a tight seal. A hose attached to the cuirasse applies cycled negative pressure that lifts and releases the anterior chest wall. The cuirasse is suitable only for infants and children with mild neuromuscular weakness and pliable chest walls. A similar negative-pressure device utilizes a plastic bag that fits snugly around the chest and operates under the same principle as the cuirasse to lift and release the chest wall.

Iron Lung

The iron lung is a device that also applies negative pressure to the child's body. The child is placed in the iron lung cylinder with his head

extending outside of the device. A cuff is placed around the neck to minimize air leaks. Negative pressure is cycled within the iron lung, facilitating chest wall movement. Ventilation is disrupted whenever the device is opened for patient care. The iron lung is suitable for children with muscular weakness who require ventilation for part of the day. Its main advantage is that it does not require a tracheostomy. However, upper airway obstruction may occur, and this risk requires ongoing evaluation. A smaller, lightweight version of this device is available for travel.

Diaphragmatic Pacing

Detailed in the management section of Ch. 418.2, diaphragm pacers may also be considered in children with spinal cord injury above C3, though the immediate advantages are less apparent than in CCHS.

Positive-Pressure Ventilators

Ideally, a ventilator intended for home use is lightweight and small, quiet so it doesn't interfere with activities of daily living or sleep, able to entrain room air, preferably has continuous flow, and has a wide range of settings (particularly for pressure, volume, pressure support, and rate) that allows ventilatory support from infancy to adulthood. Battery power for the ventilator, both internal and external, should be sufficient to permit unrestricted portability in the home and community. The equipment must also be impervious to electromagnetic interference and must be relatively easy to understand and troubleshoot. A variety of ventilators that are approved for home use are available, and familiarity with these devices is necessary to choose the best option for the individual child.

Children who are chronically ventilated via positive-pressure ventilation will require surgical placement of a tracheostomy tube. The tracheostomy tube provides stable access to the airway, a standardized interface for attaching the ventilator circuit to the patient, and the ability to easily remove airway secretions or deliver inhaled medications. Pediatric tracheostomy tubes typically have a single lumen and may have an inflatable cuff. Tracheostomy tubes with/without cuff inflation should be sized to control the air leak around the tube and promote adequate gas exchange, yet allow enough space around the tube to facilitate vocalization and prevent tracheal irritation and erosion from the tube.

When a tracheostomy tube is surgically placed, a slit opening is made in the trachea between the cartilaginous rings. Stay sutures are attached to the margins of the incision to facilitate emergent tube replacement prior to healing of the stoma tract. The tracheostomy tube is often electively changed by an otolaryngologist approximately 1 wk after initial placement, and the child is subsequently cleared for tracheostomy tube changes by the nursing staff. The child's caregivers, usually parents or family members and home nursing staff, are instructed in all aspects of tracheostomy care: stoma care, elective and emergent tracheostomy change, proper securing of the tracheostomy tube, suctioning of secretions, and recognition of tube obstruction or decannulation. The child's caregivers have to demonstrate competency with all the tasks prior to home discharge.

AIRWAY CLEARANCE

Thick, copious secretions may contribute to increased airway resistance and provide substrate for bacterial and fungal growth. Respiratory infections in turn lead to an increase in the amount of secretions and may increase viscosity, contributing to problems in airway clearance. Patients with neuromuscular weakness often have dyscoordination or absence of swallow, putting them at risk for aspiration of oral secretions or food. Reflux resulting in aspiration is also common. Additionally, many patients have poor or nonexistent cough, and some of them may have ciliary dysfunction.

Common modalities that help with clearance of secretions include postural drainage, manual or mechanical percussion or vibration, and vest or wrap percussion therapy. Force of cough may be enhanced with a cough assist device and/or abdominal binder. In addition, oropharyngeal or tracheal suctioning to remove secretions may promote airway clearance. In rare cases where airway clearance is not amenable to these measures, intermittent positive ventilation devices may be a useful adjunct.

Control of oral secretions can be achieved pharmacologically with anticholinergic drugs, localized injection of botulinum toxin (Botox), or surgical ligation of selected salivary ducts. In extreme cases, surgical tracheolaryngeal separation may be indicated. If thick, tenacious secretions are problematic, patient hydration and dosing of anticholinergic medication should be reviewed. Administration of nebulized dornase alfa or *N*-acetylcysteine, hypertonic saline, and/or sodium bicarbonate may be considered to thin secretions. In selected cases, bronchoscopy may be indicated for the removal of inspissated secretions and/or reexpansion of atelectatic pulmonary lobe or segment.

PHYSICAL THERAPY, OCCUPATIONAL THERAPY, AND SPEECH THERAPY

Therapies are very important in management of chronic respiratory failure. Potential goals for physical therapy are mobilization of the patient and strengthening of muscles, particularly truncal and abdominal muscles that are essential to pulmonary rehabilitation. Occupational therapy goals revolve around achieving or maintaining developmental milestones. Child life/developmental therapy focuses on provision of developmentally appropriate environmental stimulation and age-appropriate play. Speech therapy goals deal with oromotor skills for feeding and communication. Evaluation of swallow is a key component of therapy for children with chronic respiratory failure. Sign language is frequently utilized for communication because of delayed speech or hearing loss. Audiology specialists should be involved in the assessment of hearing, as there is a higher incidence of hearing loss in patients undergoing long-term ventilation.

INFECTIONS

Infections—tracheitis (see Chapter 385.2), bronchitis (see Chapter 391.2), and pneumonia (see Chapter 400)—are common in patients with chronic respiratory failure. Infections may be caused by community-acquired viruses (adenovirus, influenza, respiratory syncytial virus, parainfluenza, rhinovirus) or community- or hospital-acquired bacteria. Common pathogens are Gram-negative, highly antimicrobial-resistant pathogens that may cause further deterioration in pulmonary function. Bacterial infection is most likely in the presence of fever, deteriorating lung function (hypoxia, hypercarbia, tachypnea, and retractions), leukocytosis, and mucopurulent sputum. The presence of leukocytes and organisms on Gram stain of tracheal aspirate, as well as the visualization of new infiltrates on radiographs, may be consistent with bacterial infection.

Infection must be distinguished from tracheal colonization of bacteria, which is asymptomatic and associated with normal amounts of clear tracheal secretions. If infection is suspected, it must be treated with antibiotics, based on the culture and sensitivities of organisms recovered from the tracheal aspirate. Starting inhaled tobramycin and polymyxin E early may avert more serious infection. Antibiotics should be used judiciously to prevent further colonization with drug-resistant organisms. However, some patients who have recurrent infections may benefit from prophylaxis with inhaled antibiotics. Preventive measures are essential and include immunizations (influenza, pneumococcus, Haemophilus influenzae type b), passive immunity (respiratory syncytial virus), and good tracheostomy care.

MONITORING

A patient who is ventilated in the home must be electronically and/or physically monitored at all times. Infants and young children, children who are cognitively impaired, and children who are completely tracheostomy dependent for airway patency because of suprastomal obstruction must be under direct observation of the caregivers at all times. Caregivers should also closely monitor children whose pulmonary status is fragile or fluctuant. Continuous monitoring of O_2 saturation and heart rate is recommended during sleep, and either continuous or intermittent monitoring during the daytime, depending on patient stability. Patients with CCHS or pulmonary hypertension are particularly vulnerable to episodes of hypoxemia and/or hypercarbia, and

those with pulmonary hypertension are particularly susceptible to rapid drops in O_2 saturation.

Patients evaluated in pulmonary clinic for follow up should be monitored at each visit for heart rate, O_2 saturation, and transcutaneous and/or end-tidal CO_2 levels. Pulmonary function tests should be considered for those patients who are old enough and able to cooperate, usually after 5 yr of age. Serial echocardiograms should be obtained to monitor progression of pulmonary hypertension. Increased frequency of monitoring and surveillance are recommended for patients whose pulmonary status has improved and are in the process of weaning completely off ventilator support. A polysomnogram performed off the ventilator may be useful when total liberation from mechanical ventilation is being contemplated. In addition to physiologic parameters, patients must be monitored for signs of stress, agitation, and fatigue. Often these signs appear one or more days after the ventilator parameter changes.

WEANING OFF VENTILATOR SUPPORT

Patients recuperating from pulmonary disease, who are on stable ventilator settings with low positive end-expiratory pressure and minimal or no O_2 support, should be evaluated periodically for readiness to begin weaning from mechanical ventilation. Barriers to weaning may include residual lung disease, pulmonary hypertension, impaired central control of breathing, and muscle weakness. Weakness often has a multifactorial etiology. Factors such as underlying neuromuscular disease, use of sedatives, analgesics, steroids and muscle relaxants, and prolonged immobility, as well as utilization of mechanical ventilation, may downregulate mitochondrial activity in the respiratory muscles, and more so the diaphragm, and produce muscular changes resulting in weakness. Consequently, it is important to avoid 24 hr/day patient synchrony with ventilation and titrate the amount of ventilator support to prevent fatigue, yet facilitate spontaneous breathing.

When transitioning from full mechanical ventilatory support to spontaneous breathing, conditioning of the respiratory muscles can be achieved by several methods: gradual decrease of mechanical support by decreasing the ventilator pressures and/or rate, sprints of pressure support ventilation, retraining of the respiratory muscles with breathing exercises against an obstructed airway, and spontaneous breathing sprints off the ventilator. The weaning program may be initiated prior to initial hospital discharge or during follow up clinic visits. An initial weaning schedule may consist of 15 min sprints of free breathing off the ventilator up to 3 times/day while directly observed by caregiver and monitoring of respiratory parameters. The sprints are lengthened gradually with continued monitoring in the home and during frequent clinic visits. Additional factors that reflect tolerance of increased work of breathing, including weight gain, energy levels, general behavior and sleep patterns, are also monitored carefully. When the child has completely weaned off ventilator support while awake and is only on the ventilator approximately 6 hr nightly during sleep, a polysomnogram study performed off the ventilator may be considered prior to complete liberation from the mechanical ventilation device.

DISCHARGE PROCESS

The discharge process for a child going home for the first time on a ventilator is complex. A multidisciplinary, coordinated team approach is needed to develop an individualized, comprehensive plan that addresses medical, psychosocial, developmental, educational, and safety issues. The child should be transitioned to a ventilator suitable for home use that allows portability as well as adequate ventilation. Depending on the type of ventilation employed, a tracheostomy is typically placed to promote comfort and provide a stable airway as soon as the decision for long-term ventilation is made. Medical management should also focus on transitioning oxygen and ventilator parameters to settings appropriate for home care. The ventilated child must demonstrate medical stability at a level that can be safely managed at home; interventions to maintain patient stability should be minimal 1-2 wk before discharge.

Nutrition should be optimized to promote growth yet minimize excessive weight gain and carbon dioxide production. The nutritional requirements of a ventilated child are frequently decreased due to the supported work of breathing. The ventilated child often has problems with uncoordinated swallowing and oral aversion secondary to intubation. Speech therapy should be introduced early to begin oromotor therapy and return of swallow. Many children require gastrostomy tube placement to replace or supplement oral intake. Evaluation and management of reflux and the risk of aspiration should also be considered. Some children with severe reflux may require jejunal feedings. Communication devices to augment speech and introduction of sign language for speech and hearing impaired should be part of the planning.

Training of family caregivers should be initiated early in the discharge process and should be provided by nurses, respiratory care practitioners, and physical, occupational, and speech therapists knowledgeable in the individual child's care. Home caregivers, typically the parents or family members and home nursing staff, are instructed in all aspects of the child's care, including tracheostomy tube changes and care, tube feedings and care, medication administration, ventilator management and troubleshooting, emergency response, and cardiopulmonary resuscitation. Caregiver independence in delivery of care at the bedside and while transporting the child should be emphasized. Special emphasis should be placed on safety and the appropriate response in the event of an emergency. A standardized emergency bag containing critical tracheostomy and ventilator supplies should accompany the child at all times. A minimum of 2 family members should complete instruction and demonstrate their competency by independently providing their child's care for a 24-48 hr period prior to discharge.

Community agencies are identified for provision of home support services, typically including a nursing agency and equipment vendor. The nursing agency may provide private duty nursing services. Home care nurses should have pediatric tracheostomy and ventilator experience and be well versed in the individual child's care before home discharge. An equipment vendor who can provide the ventilator, medical equipment and supplies, and maintenance/repair service should be selected. A care conference involving the hospital team, funding agency, home nursing agency, equipment vendor, and family caregivers should take place before discharge. The conference is critical for coordination of last-minute details and facilitation of a smooth transition to home.

OUTPATIENT FOLLOW UP

Provision of ongoing medical support to the child and family after discharge is essential. The primary care provider in the community has the central role in coordination of care, and provision of well-child, acute, and chronic care, with the exception of ventilatory management. Equally important is the establishment of lines of communication between the primary care provider and the pulmonary/critical care specialists managing ventilator care, and the provision of timely access for advice and troubleshooting during the intervals between respiratory multidisciplinary clinic visits.

The purpose of the respiratory multidisciplinary clinic is to monitor the patient's progress, ensure that the ventilatory support is sufficient to promote growth and development and, when appropriate, to initiate or continue the ventilator weaning process. Physicians and/or advanced practice nurses who are well versed in ventilator care, typically pulmonary or critical care specialists, as well as respiratory care practitioners, evaluate the patient in clinic. Clinical nutrition, social work, and case management services should also be readily available.

The frequency of the clinic visits depends on the stability of the patient and the frequency of medical interventions needed to maintain clinical stability. A patient discharged from the hospital for the first time on a ventilator is typically evaluated in clinic within a month and may require monthly follow-up visits. Once the child is stable, the frequency decreases to every 3-6 mo. Older long-term patients who are no longer having major growth spurts are typically scheduled for annual visits. Patients who are actively weaning from the ventilator are seen more frequently. During the clinic visit respiratory monitoring is obtained while the child is on the ventilator and, if medically indicated,

off the ventilator, and repeated whenever ventilator adjustments are made. Whenever possible, readings obtained from home monitoring devices are compared with clinic monitoring to determine correlation. Recommendations regarding the child's ventilator management are communicated to the primary care provider by letter or phone call after each clinic visit.

TRANSITION OF CARE

The pulmonary team initiates ongoing discussions regarding self-care responsibilities and transitioning of medical care to adult providers with the adolescent and his parents when the patient reaches the early teens. Discussion about self-care should take into consideration realistic expectations about the adolescent's physical and cognitive capabilities. The actual transition of care occurs for most young adults at age 18-21 yr, and includes referral to an internist as well as an adult pulmonologist. Transition of medical care also includes transition from pediatric to adult support services for funding sources and nursing care. Ideally, an outpatient visit that includes current and future adult medical providers together is completed to facilitate communication and formally transition care.

Chapter 419

Extrapulmonary Diseases with Pulmonary Manifestations

Susanna A. McColley

Respiratory symptoms commonly originate from extrapulmonary processes. The respiratory system adapts to metabolic demands and is exquisitely responsive to cortical input; therefore, **tachypnea** is common in the presence of metabolic stress such as fever, whereas dyspnea may be related to anxiety. **Cough** most commonly arises from upper or lower respiratory tract disorders, but it can originate from the central nervous system, as with cough tic or psychogenic cough, and it can be a prominent symptom in children with gastroesophageal reflux disease. **Chest pain** does not commonly arise from pulmonary processes in otherwise healthy children but more often has a neuromuscular or inflammatory etiology. **Cyanosis** can be caused by cardiac or hematologic disorders, and **dyspnea** and **exercise intolerance** can have a number of extrapulmonary causes. These disorders may be suspected on the basis of the history and physical examination, or they may be considered in children in whom diagnostic studies have atypical findings or who show poor response to usual therapy. Table 419-1 lists more common causes of such symptoms.

EVALUATION

In the evaluation of a child or adolescent with respiratory symptoms, it is important to obtain a detailed past medical history, family history, and review of systems to evaluate the possibility of extrapulmonary origin. A comprehensive physical examination is also essential in obtaining clues to extrapulmonary disease.

Disorders of other organ systems, and many systemic diseases, can have significant respiratory system involvement. Although it is most common to encounter these complications in patients with known diagnoses, respiratory system disease is sometimes the sole or most prominent symptom at the time of presentation. Acute aspiration during feeding can be the presentation of neuromuscular disease in an infant who initially appears to have normal muscle tone and development. Complications can be life-threatening, particularly in immunocompromised patients. The onset of respiratory findings may be insidious; for example, pulmonary vascular involvement in patients with systemic vasculitis may appear as an abnormality in diffusing capacity of the lung for carbon monoxide before the onset of symptoms. Table 419-2 lists disorders that commonly have respiratory complications.

Bibliography is available at Expert Consult.

Table 419-1 Respiratory Signs and Symptoms Originating from Outside the Respiratory Tract

SIGN OR SYMPTOM	NONRESPIRATORY CAUSE(S)	PATHOPHYSIOLOGY	CLUES TO DIAGNOSIS
Chest pain	Cardiac disease	Inflammation (pericarditis), ischemia (anomalous coronary artery, vascular disease)	Precordial pain, friction rub on examination; exertional pain, radiation to arm or neck
Chest pain	Gastroesophageal reflux disease	Esophageal inflammation and/or spasm	Heartburn, abdominal pain
Cyanosis	Congenital heart disease Methemoglobinemia	Right-to-left shunt Increased levels of methemoglobin interfere with delivery of oxygen to tissues	Neonatal onset, lack of response to oxygen Drug or toxin exposure, lack of response to oxygen
Dyspnea	Toxin exposure, drug side effect, or overdose	Variable, but often metabolic acidosis	Drug or toxin exposure confirmed by history or toxicology screen, normal oxygen saturation measured by pulse oximetry
	Anxiety, panic disorder	Increased respiratory drive and increased perception of respiratory efforts	Occurs during stressful situation, other symptoms of anxiety or depression

Table 419-1 Respiratory Signs and Symptoms Originating from Outside the Respiratory Tract—cont'd

SIGN OR SYMPTOM	NONRESPIRATORY CAUSE(S)	PATHOPHYSIOLOGY	CLUES TO DIAGNOSIS
Exercise intolerance	Anemia	Inadequate oxygen delivery to tissues	Pallor, tachycardia, history of bleeding, history of inadequate diet
Exercise intolerance	Deconditioning	Self-explanatory	History of inactivity, obesity
Hemoptysis	Nasal bleeding	Posterior flow of bleeding causes appearance of pulmonary origin	History and physical findings suggest nasal source; normal chest examination, and chest radiography
	Upper gastrointestinal tract bleeding	Hematemesis mimics hemoptysis	History and physical examination suggest gastrointestinal source, normal chest examination and chest radiography
Wheezing, cough, dyspnea	Congenital or acquired cardiac disease	Pulmonary overcirculation (atrioseptal defect, ventriculoseptal defect, patent ductus arteriosus), left ventricular dysfunction	Murmur Refractory to bronchodilators Radiographic changes (prominent pulmonary vasculature, pulmonary edema)
Wheezing, cough	Gastroesophageal reflux disease	Laryngeal and bronchial response to stomach contents Vagally mediated bronchoconstriction	Emesis, pain, heartburn Refractory to bronchodilators

Table 419-2 Disorders with Frequent Respiratory Tract Complications

UNDERLYING DISORDER(S)	RESPIRATORY COMPLICATIONS	DIAGNOSTIC TESTS
Autoimmune disorders	Pulmonary vascular disease, restrictive lung disease, pleural effusion (especially systemic lupus erythematosus), upper airway disease (Wegener granulomatosis)	Spirometry, lung volume determination, oximetry, diffusing capacity of the lung for carbon monoxide, chest radiography, upper airway endoscopy, and/or CT
Central nervous system disease (static or progressive)	Aspiration of oral or gastric contents	Chest radiography, videofluoroscopic swallowing study, esophageal pH probe, fiberoptic bronchoscopy
Immunodeficiency	Infection, bronchiectasis	Chest radiography, fiberoptic bronchoscopy, chest CT
Liver disease	Pleural effusion, hepatopulmonary syndrome	Chest radiography, assessment of orthodeoxia
Malignancy and its therapies	Infiltration, metastasis, malignant or infectious effusion, parenchymal infection, graft-versus-host disease (bone marrow transplant)	Chest radiography, chest CT, fiberoptic bronchoscopy, lung biopsy
Neuromuscular disease	Hypoventilation, atelectasis, pneumonia	Spirometry, lung volume determination, respiratory muscle force measurements
Obesity	Restrictive lung disease, obstructive sleep apnea syndrome, asthma	Spirometry, lung volume determination, nocturnal polysomnography

The Cardiovascular System

PART XX

Section 1 Developmental Biology of the Cardiovascular System

Chapter 420 Cardiac Development

Daniel Bernstein

Knowledge of the cellular and molecular mechanisms of cardiac development is necessary for understanding congenital heart defects and will be even more important in developing strategies for prevention, whether cell or molecular therapies or fetal cardiac interventional procedures. Cardiac defects have traditionally been grouped by common morphologic patterns: for example, abnormalities of the outflow tracts (conotruncal lesions such as tetralogy of Fallot and truncus arteriosus) and abnormalities of atrioventricular septation (primum atrial septal defect, complete atrioventricular canal defect). These morphologic categories may be revised or eventually supplanted by new categories as our understanding of the genetic basis of congenital heart disease progresses.

Bibliography is available at Expert Consult.

420.1 Early Cardiac Morphogenesis

Daniel Bernstein

In the early presomite embryo, the first identifiable cardiac progenitor cell clusters are arranged in the anterior lateral plate mesoderm on both sides of the embryo's central axis; these clusters form paired cardiac tubes by 18 days of gestation. The paired tubes fuse in the midline on the ventral surface of the embryo to form the primitive heart tube by 22 days. This straight heart tube is composed of an outer myocardial layer, an inner endocardium, and a middle layer of extracellular matrix known as the cardiac jelly. There are 2 distinct cell lineages: the primary heart field provides precursor cells for the left ventricle, whereas the secondary heart field provides precursors for the atria and right ventricle. Premyocardial cells, including epicardial cells and cells derived from the neural crest, continue their migration into the region of the heart tube. Regulation of this early phase of cardiac morphogenesis is controlled in part by the interaction of specific signaling molecules or ligands, usually expressed by 1 cell type, with specific receptors, usually expressed by another cell type. Positional information is conveyed to the developing cardiac mesoderm by factors such as retinoids (isoforms of vitamin A), which bind to specific nuclear receptors and regulate gene transcription. Migration of epithelial cells into the developing heart tube is directed by extracellular matrix proteins (such as fibronectin) interacting with cell surface receptors (the integrins). Other important regulatory molecules include bone morphogenetic protein 2 (BMP2); fibroblast growth factor 4 (FGF4); the transcription factors Nkx2.5, GATA4, Mesp1, and Mesp2; and members of the Wnt/β-catenin signaling pathway. The clinical importance of these ligands is revealed by the spectrum of **cardiac teratogenic** effects caused by the retinoid-like drug isotretinoin.

As early as 20-22 days, before cardiac looping, the embryonic heart begins to contract and exhibit phases of the cardiac cycle that are surprisingly similar to those in the mature heart. Morphologists initially identified segments of the heart tube that were believed to correspond to structures in the mature heart (Fig. 420-1): the sinus venosus and atrium (right and left atria), the primitive ventricle (left ventricle), the bulbus cordis (right ventricle), and the truncus arteriosus (aorta and pulmonary artery). However, this model is oversimplified. Only the trabecular (most heavily muscularized) portions of the left ventricular myocardium are present in the early cardiac tube; the cells that will become the inlet portion of the left ventricle migrate into the cardiac tube at a later stage (after looping is initiated). Even later to appear are the primordial cells that give rise to the great arteries (truncus arteriosus), including cells derived from the neural crest, which are not present until after cardiac looping is complete. Chamber-specific transcription factors participate in the differentiation of the right and left ventricles. The basic helix-loop-helix (bHLH) transcription factor dHAND is expressed in the developing right ventricle; disruption of this gene or of other transcriptional factors such as myocyte enhancer factors 2C (MEF2C) in mice leads to hypoplasia of the right ventricle. The transcription factor eHAND is expressed in the developing left ventricle and conotruncus and is also critical to their development. How regulation of developmentally coordinated groups of genes is achieved has been the focus of recent research. One mechanism is through the expression of small noncoding RNAs known as microRNAs, each of which regulate the expression of multiple target genes. Another is through modifications in chromatin, the DNA scaffolding which acts as a controller of gene expression. Chromatin remodeling mediated by factors such as Brg1, Chd7, histone demethylases, and methyltransferases is associated with cardiac developmental defects.

420.2 Cardiac Looping

Daniel Bernstein

At approximately 22-24 days, the heart tube begins to bend ventrally and toward the right (see Fig. 420-1). The heart is the first organ to escape from the bilateral symmetry of the early embryo. Looping brings the future left ventricle leftward and in continuity with the sinus venosus (future left and right atria), whereas the future right ventricle is shifted rightward and in continuity with the truncus arteriosus (future aorta and pulmonary artery). This pattern of development explains the relatively common occurrence of the cardiac anomalies double-outlet right ventricle and double-inlet left ventricle and the extreme rarity of double-outlet left ventricle and double-inlet right ventricle (see Chapter 430.5). When cardiac looping is abnormal (situs inversus, heterotaxia), the incidence of serious cardiac malformations is high and there are usually associated abnormalities in the left-right (L-R) patterning of the lungs and abdominal viscera.

Potential mechanisms of cardiac looping include differential growth rates for myocytes on the convex vs the concave surface of the curve, differential rates of programmed cell death (apoptosis), and mechanical forces generated within myocardial cells via their actin cytoskeleton. The signal for this directionality is contained in a concentration gradient between the right and left sides of the embryo in the expression of critical signaling molecules. A number of signaling

pathways have been identified as regulators of this L-R asymmetry, including sonic hedgehog (SHH), transforming growth factor-β, nodal, and LR dynein. Interestingly, mice in which the LR dynein gene has been inactivated display random L-R orientation of the heart and abdominal viscera, with 50% of their hearts looping to the right and 50% looping to the left.

420.3 Cardiac Septation

Daniel Bernstein

When looping is complete, the external appearance of the heart is similar to that of a mature heart; internally, the structure resembles a single tube, although it now has several bulges resulting in the appearance of primitive chambers. The common atrium (comprising both the right and left atria) is connected to the primitive ventricle (future left ventricle) via the atrioventricular canal. The primitive ventricle is connected to the bulbus cordis (future right ventricle) via the bulboventricular foramen. The distal portion of the bulbus cordis is connected to the truncus arteriosus via an outlet segment (the conus).

The heart tube now consists of several layers of myocardium and a single layer of endocardium separated by cardiac jelly, an acellular extracellular matrix secreted by the myocardium. Septation of the heart begins at approximately day 26 with the ingrowth of large tissue masses, the endocardial cushions, at both the atrioventricular and conotruncal junctions (see Fig. 420-1). These cushions consist of protrusions of cardiac jelly, which, in addition to their role in development, also serve a physiologic function as primitive heart valves. Endocardial cells dedifferentiate and migrate into the cardiac jelly in the region of the endocardial cushions, eventually becoming mesenchymal cells that will form part of the atrioventricular valves.

Complete septation of the atrioventricular canal occurs with fusion of the endocardial cushions. Most of the atrioventricular valve tissue

is derived from the ventricular myocardium in a process involving undermining of the ventricular walls. Because this process occurs asymmetrically, the tricuspid valve annulus sits closer to the apex of the heart than the mitral valve annulus does. Physical separation of these 2 valves produces the atrioventricular septum, the absence of which is the primary common defect in patients with **atrioventricular canal defects** (see Chapter 426.5). If the process of undermining is incomplete, the right atrioventricular valve may not separate normally from the ventricular myocardium, a possible cause of **Ebstein anomaly** (see Chapter 430.7).

Septation of the atria begins at ≈30 days with growth of the septum primum downward toward the endocardial cushions (see Fig. 420-1). The orifice that remains is the ostium primum. The endocardial cushions then fuse and, together with the completed septum primum, divide the atrioventricular canal into right and left segments. A 2nd opening appears in the posterior portion of the septum primum, the ostium secundum, and it allows a portion of the fetal venous return to the right atrium to pass across to the left atrium. Finally, the septum secundum grows downward, just to the right of the septum primum. Together with a flap of the septum primum, the ostium secundum forms the foramen ovale, through which fetal blood passes from the inferior vena cava to the left atrium (see Chapter 421).

Septation of the ventricles begins at about embryonic day 25 with protrusions of endocardium in both the inlet (primitive ventricle) and outlet (bulbus cordis) segments of the heart. The inlet protrusions fuse into the bulboventricular septum and extend posteriorly toward the inferior endocardial cushion, where they give rise to the inlet and trabecular portions of the interventricular septum. **Ventricular septal defects** can occur in any portion of the developing interventricular septum (see Chapter 426.6). The outlet or conotruncal septum develops from ridges of cardiac jelly, similar to the atrioventricular cushions. These ridges fuse to form a spiral septum that brings the future pulmonary artery into communication with the anterior and rightward right ventricle and the future aorta into communication with the posterior and leftward left ventricle. Differences in cell growth of the outlet septum lead to lengthening of the segment of smooth muscle beneath the pulmonary valve (conus), a process that separates the tricuspid and pulmonary valves. In contrast, disappearance of the segment beneath the aortic valve leads to fibrous continuity of the mitral and aortic valves. Defects in these processes are responsible for **conotruncal** and **aortic arch defects** (truncus arteriosus, tetralogy of Fallot, pulmonary atresia, double-outlet right ventricle, interrupted aortic arch), a group of cardiac anomalies often associated with deletions of the DiGeorge critical region of chromosome 22q11 (see Chapters 423 and 424). The transcription factor Tbx1 has been implicated as a candidate gene, which may be responsible for DiGeorge syndrome. Several genes have been implicated in valve formation, including *Ptpn11*, which encodes the tyrosine phosphatase Shp-2, and when present in a mutated from is one of the genes responsible for **Noonan syndrome**, associated with pulmonary valve stenosis; and NOTCH1, a regulator of cell differentiation that has been associated with aortic valve disease.

420.4 Aortic Arch Development

Daniel Bernstein

The aortic arch, head and neck vessels, proximal pulmonary arteries, and ductus arteriosus develop from the aortic sac, arterial arches, and dorsal aortae. When the straight heart tube develops, the distal outflow portion bifurcates into the right and left 1st aortic arches, which join the paired dorsal aortae (Fig. 420-2). The dorsal aortae will fuse to form the descending aorta. The proximal aorta from the aortic valve to the left carotid artery arises from the aortic sac. The 1st and 2nd arches largely regress by about 22 days, with the 1st aortic arch giving rise to the maxillary artery and the 2nd to the stapedial and hyoid arteries. The 3rd arches participate in the formation of the innominate artery and the common and internal carotid arteries. The right 4th arch gives rise to the innominate and right subclavian arteries, and the left 4th arch participates in formation of the segment of the aortic arch between

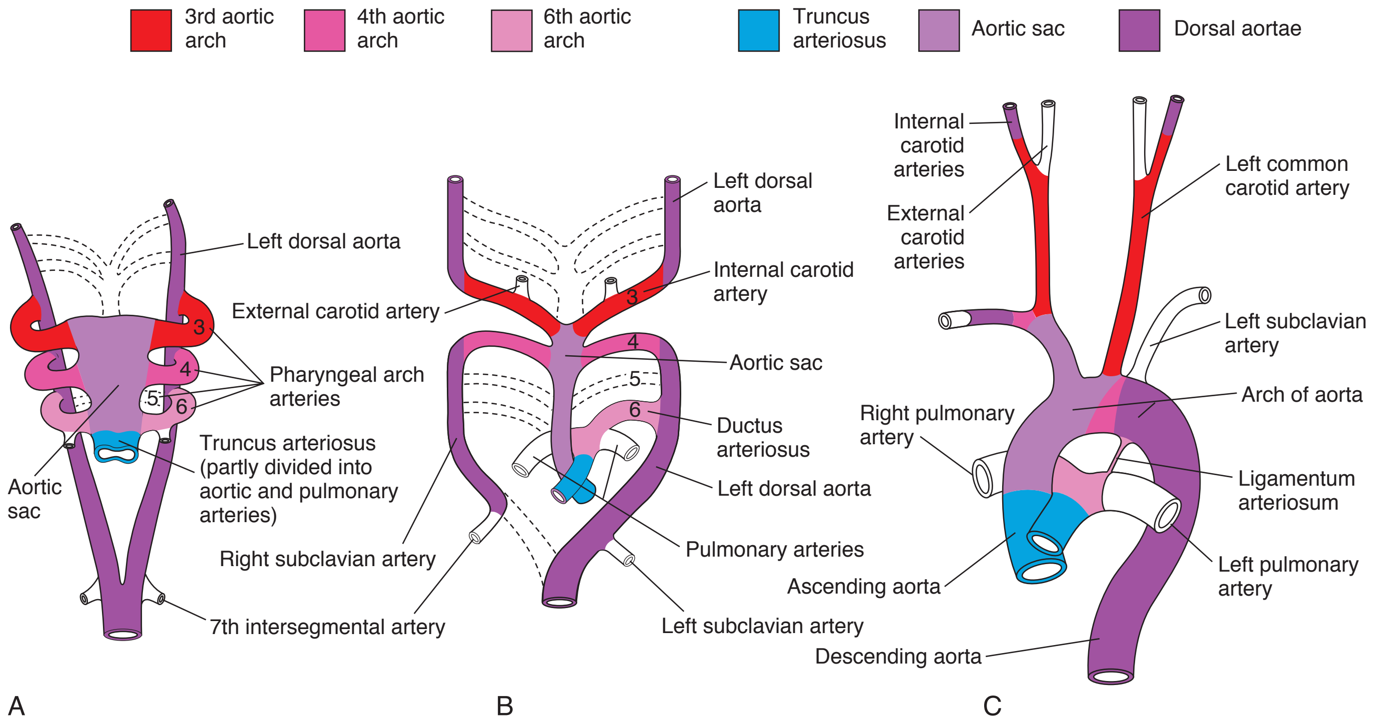

Figure 420-2 Schematic drawings illustrating the changes that result during transformation of the truncus arteriosus, aortic sac, aortic arches, and dorsal aortae into the adult arterial pattern. The vessels that are not shaded or colored are not derived from these structures. **A,** Aortic arches at 6 wk; by this stage the 1st 2 pairs of aortic arches have largely disappeared. **B,** Aortic arches at 7 wk; the parts of the dorsal aortae and aortic arches that normally disappear are indicated by broken lines. **C,** Arterial vessels of a 6 mo old infant. *(From Moore KL, Persaud TVN, Torchia M: The developing human, Philadelphia, 2007, Elsevier.)*

the left carotid artery and the ductus arteriosus. The 5th arch does not persist as a major structure in the mature circulation. The 6th arches join the more distal pulmonary arteries, with the right 6th arch giving rise to a portion of the proximal right pulmonary artery and the left 6th arch giving rise to the ductus arteriosus. The aortic arch between the ductus arteriosus and the left subclavian artery is derived from the left-sided dorsal aorta, whereas the aortic arch distal to the left subclavian artery is derived from the fused right and left dorsal aortae. Abnormalities in development of the paired aortic arches are responsible for **right aortic arch, double aortic arch,** and **vascular rings** (see Chapter 432.1).

420.5 Cardiac Differentiation

Daniel Bernstein

The process by which the totipotential cells of the early embryo become committed to specific cell lineages is differentiation. Precardiac mesodermal cells differentiate into mature cardiac muscle cells with an appropriate complement of cardiac-specific contractile elements, regulatory proteins, receptors, and ion channels. Expression of the contractile protein myosin occurs at an early stage of cardiac development, even before fusion of the bilateral heart primordia. Differentiation in these early mesodermal cells is regulated by signals from the anterior endoderm, a process known as *induction*. Several putative early signaling molecules include fibroblast growth factor, activin, and insulin. Signaling molecules interact with receptors on the cell surface; these receptors activate 2nd messengers, which, in turn, activate specific nuclear transcription factors (GATA-4, MEF2, Nkx, bHLH, and the retinoic acid receptor family) that induce the expression of specific gene products to regulate cardiac differentiation. Some of the primary disorders of cardiac muscle, the **cardiomyopathies,** may be related to defects in some of these signaling molecules (see Chapter 439).

Developmental processes are chamber specific. Early in development, ventricular myocytes express both ventricular and atrial isoforms of several proteins, such as atrial natriuretic peptide (ANP) and myosin light chain (MLC). Mature ventricular myocytes do not express ANP and express only a ventricular-specific MLC 2v isoform, whereas mature atrial myocytes express ANP and an atrial-specific MLC 2a isoform. Heart failure (see Chapter 442), volume overload (see Chapters 426 and 428), and pressure overload hypertrophy (see Chapter 427) are associated with a recapitulation of fetal cell phenotypes in which mature myocytes reexpress fetal proteins. Because different isoforms have different contractile behavior (fast vs. slow activation, high vs. low adenosine triphosphatase activity), expression of different isoforms may have important functional consequences.

The extent to which stem cells can be made to differentiate into cardiac muscle cells is the focus of investigation in the field of regenerative cardiology. The demonstration that fully differentiated adult cells (e.g., skin fibroblasts or peripheral blood mononuclear cells) can be *reprogrammed* into induced pluripotential stem cells and then *differentiated* into beating cardiomyocytes in vitro, has opened up many new avenues to study cardiovascular disease. Some investigators believe that there are precursor cells (cardiac stem cells) resident within the myocardium that can replace damaged myocytes, although at a rate too slow to be clinically useful. Scientists are working on trying to stimulate these cells with the proper regulatory factors, thus inducing them to regenerate damaged cardiac muscle. Others are investigating whether circulating stem cells, bone marrow–derived cells, or the factors they secrete can support cardiac regeneration. Eventually, stem cells grown on biomechanical scaffolds may be used to build a replacement ventricle for patients with hypoplastic left or right heart.

420.6 Developmental Changes in Cardiac Function

Daniel Bernstein

During development, the composition of the myocardium undergoes profound changes that result in an increase in the number and size of myocytes. During prenatal life, this process involves myocyte division (hyperplasia), whereas after the 1st few postnatal weeks, subsequent cardiac growth occurs mostly by an increase in myocyte size (hypertrophy). The myocytes themselves change shape from round to cylindrical, the proportion of myofibrils (which contain the contractile apparatus) increases, and the myofibrils become more regular in their orientation.

The plasma membrane (known as the *sarcolemma* in myocytes) is the location of the ion channels and transmembrane receptors that regulate the exchange of chemical information from the cell surface to the cell interior. Ion fluxes through these channels control the processes of depolarization and repolarization. Developmental changes have been described for the sodium-potassium pump, the sodium-hydrogen exchanger, and voltage-dependent calcium channels. As the myocyte matures, extensions of the sarcolemma develop toward the interior of the cell (the t-tubule system), which dramatically increases its surface area and enhances rapid activation of the myocyte. Regulation of the membrane's α- and β-adrenergic receptors with development enhances the ability of the sympathetic nervous system to control cardiac function as the heart matures.

The sarcoplasmic reticulum (SR), a series of tubules surrounding the myofibrils, controls the intracellular calcium concentration. A series of pumps regulate calcium release to the myofibrils for initiation of contraction (ryanodine-sensitive calcium channel) and calcium uptake for initiation of relaxation (adenosine triphosphate–dependent SR calcium pump). In immature hearts, this SR calcium transport system is less well developed, and such hearts consequently have an increased dependence on transport of calcium from outside the cell for contraction. In a mature heart, the majority of the calcium to activate contraction comes from the SR. This developmental phenomenon may explain the sensitivity of the infant heart to sarcolemmal calcium channel blockers such as verapamil, which can result in a marked depression in contractility (see Chapter 435).

The major contractile proteins (myosin, actin, tropomyosin, and troponin) are organized into the functional unit of cardiac contraction, the sarcomere. Each has several isoforms that are expressed differentially by location (atrium vs. ventricle) and by developmental stage (embryo, fetus, newborn, adult).

Changes in myocardial structure and myocyte biochemistry result in easily quantifiable differences in cardiac function with development. Fetal cardiac function is less responsive to changes in both preload (filling volume) and afterload (systemic resistance). The most effective means of increasing ventricular function in a fetus is through increasing the heart rate. After birth and with further maturation, preload and afterload play an increasing role in regulating cardiac function. The rate of cardiac relaxation is also developmentally regulated. The decreased ability of the immature SR calcium pump to remove calcium from the contractile apparatus is manifested as a decreased ability of the fetal heart to enhance relaxation in response to sympathetic stimulation.

Chapter 421

The Fetal to Neonatal Circulatory Transition

421.1 The Fetal Circulation

Daniel Bernstein

The human fetal circulation and its adjustments after birth are similar to those of other large mammals, although rates of maturation differ. In the fetal circulation, the right and left ventricles exist in a parallel circuit, as opposed to the series circuit of a newborn or adult (Fig. 421-1*A*). In the fetus, the placenta provides for gas and metabolite exchange. Because the lungs do not provide gas exchange, the pulmonary vessels are vasoconstricted, diverting blood away from the pulmonary circulation. Three cardiovascular structures unique to the fetus are important for maintaining this parallel circulation: the ductus venosus, foramen ovale, and ductus arteriosus.

The placenta is not as efficient an oxygen exchange organ as the lungs, so that umbilical venous Po_2 (the highest level of oxygen provided to the fetus) is only about 30-35 mm Hg. Approximately 50% of the umbilical venous blood enters the hepatic circulation, whereas the rest bypasses the liver and joins the inferior vena cava via the ductus venosus, where it partially mixes with poorly oxygenated inferior vena cava blood derived from the lower part of the fetal body. This combined lower body plus umbilical venous blood flow (Po_2 of ≈26-28 mm Hg) enters the right atrium and is preferentially directed by a flap of tissue at the right atrial–inferior vena caval junction, the eustachian valve, across the foramen ovale to the left atrium (see Fig. 421-1*B*). This is the major source of left ventricular blood flow, as pulmonary venous return is minimal. Left ventricular blood is then ejected into the ascending aorta where it supplies predominantly the fetal upper body and brain.

Fetal superior vena cava blood, which is considerably less oxygenated (Po_2 of 12-14 mm Hg), enters the right atrium and preferentially flows across the tricuspid valve, rather than the foramen ovale, into the right ventricle. From the right ventricle, the blood is ejected into the pulmonary artery. Because the pulmonary arterial circulation is vasoconstricted, only approximately 5% of right ventricular outflow enters the lungs. The major portion of this blood bypasses the lungs and flows right-to-left through the ductus arteriosus into the descending aorta to perfuse the lower part of the fetal body, including providing flow to the placenta via the 2 umbilical arteries. Thus, the upper part of the fetal body (including the coronary and cerebral arteries and those to the upper extremities) is perfused exclusively from the left ventricle with blood that has a slightly higher Po_2 than the blood perfusing the lower part of the fetal body, which is derived mostly from the right ventricle. Only a small volume of blood from the ascending aorta (10% of fetal cardiac output) flows all the way around the aortic arch (aortic isthmus) to the descending aorta.

The **total fetal cardiac output**—the combined output of both the left and right ventricles—is ≈450 mL/kg/min. Approximately 65% of descending aortic blood flow returns to the placenta; the remaining 35% perfuses the fetal organs and tissues. In the sheep fetus, where most of these circulatory pathways were studied, right ventricular output is approximately 2 times that of the left ventricle. In the human fetus, which has a larger percentage of blood flow going to the brain, right ventricular output is probably closer to 1.3 times left ventricular flow. Thus, during fetal life the right ventricle is not only pumping against systemic blood pressure but is also performing a greater volume of work than the left ventricle.

It has been postulated that blood flow is an important determinant of growth of fetal cardiac chambers, valves, and blood vessels. Thus, in

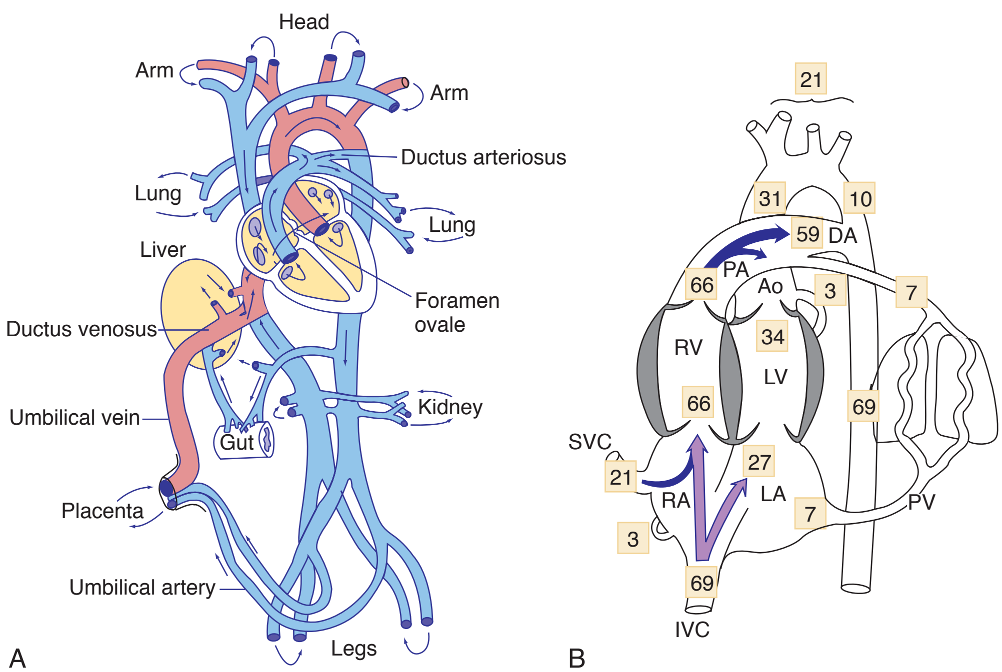

Figure 421-1 **A,** The human circulation before birth (partly after Dawes). Red indicates more highly oxygenated blood, and arrows indicate the direction of flow. More highly oxygenated blood from the placenta passes through the foramen ovale from the right to the left atrium, thus bypassing the lungs. **B,** Percentages of combined ventricular output that return to the fetal heart, that are ejected by each ventricle, and that flow through the main vascular channels. Figures are those obtained from studies of late-gestation fetal lambs. Ao, aorta; DA, ductus arteriosus; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary veins; RA, right atrium; RV, right ventricle; SVC, superior vena cava. *(From Rudolph AM:* Congenital diseases of the heart, *Chicago, 1974, Year Book.)*

the presence of a narrowing (stenosis) of an upstream structure such as the mitral valve, flow downstream into the left ventricle is limited and left ventricular growth may be compromised, leading to hypoplastic left heart syndrome (see Chapter 431.10). Similarly, stenosis of a downstream structure such as the aortic valve can similarly disrupt flow into the left ventricle and lead to hypoplastic left-heart syndrome. Fetal cardiac interventional treatments, currently experimental, are aimed at opening stenotic aortic valves in mid-gestation fetuses, and allowing more normal left ventricular growth.

421.2 The Transitional Circulation

Daniel Bernstein

At birth, mechanical expansion of the lungs and an increase in arterial Po_2 result in a rapid decrease in pulmonary vascular resistance. Concomitantly, removal of the low-resistance placental circulation leads to an increase in systemic vascular resistance. The output from the right ventricle now flows entirely into the pulmonary circulation, and because pulmonary vascular resistance becomes lower than systemic vascular resistance, the shunt through the ductus arteriosus reverses and becomes left to right. In the course of several days, the high arterial Po_2 constricts and eventually closes the ductus arteriosus, which eventually becomes the ligamentum arteriosum. The increased volume of pulmonary blood flow returning to the left atrium from the lungs increases left atrial volume and pressure sufficiently to close the flap of the foramen ovale functionally, although the foramen may remain probe patent for several years.

Removal of the placenta from the circulation also results in closure of the ductus venosus. The left ventricle is now coupled to the high-resistance systemic circulation, and its wall thickness and mass begin to increase. In contrast, the right ventricle is now coupled to the low-resistance pulmonary circulation, and its wall thickness and mass decrease. The left ventricle, which in the fetus pumped blood only to the upper part of the body and brain, must now deliver the entire systemic cardiac output (≈350 mL/kg/min), an almost 200% increase in output. This marked increase in left ventricular performance is achieved through a combination of hormonal and metabolic signals, including an increase in the level of circulating catecholamines and in the density of myocardial β-adrenergic receptors through which catecholamines have their effect.

When congenital structural cardiac defects are superimposed on these dramatic physiologic changes, they often impede this smooth transition and markedly increase the burden on the newborn myocardium. In addition, because the ductus arteriosus and foramen ovale do not close completely at birth, they may remain patent in certain congenital cardiac lesions. Patency of these fetal pathways may either provide a lifesaving pathway for blood to bypass a congenital defect (a patent ductus in pulmonary atresia or coarctation of the aorta or a foramen ovale in transposition of the great vessels) or present an additional stress to the circulation (patent ductus arteriosus in a premature infant, pathway for right-to-left shunting in infants with pulmonary hypertension). Therapeutic agents may either maintain these fetal pathways (prostaglandin E_1) or hasten their closure (indomethacin).

421.3 The Neonatal Circulation

Daniel Bernstein

At birth, the fetal circulation must immediately adapt to extrauterine life as gas exchange is transferred from the placenta to the lungs (see Chapter 101.1). Some of these changes are virtually instantaneous with the first breath, whereas others develop over a period of hours or weeks. With the onset of ventilation, pulmonary vascular resistance is markedly decreased as a consequence of both active (Po_2-related) and passive (mechanical related) pulmonary vasodilation. In a normal neonate, closure of the ductus arteriosus and the fall in pulmonary vascular resistance decreases pulmonary arterial and right ventricular pressures. The largest decline in pulmonary resistance from the high fetal levels to the low "adult" levels in the human infant at sea level usually occurs within the 1st 2-3 days but may be prolonged for 7 days or more. Over the next several weeks of life, pulmonary vascular resistance decreases even further, secondary to a remodeling of the pulmonary vasculature, including thinning of the vascular smooth muscle and recruitment of new vessels. This decrease in pulmonary vascular resistance significantly influences the timing of the clinical appearance of many congenital heart lesions that are dependent on the relative levels of systemic and pulmonary vascular resistances. The left-to-right shunt through an large ventricular septal defect may be minimal in the 1st wk after birth when pulmonary vascular resistance is still high. As pulmonary resistance decreases in the next week or 2, the volume of the left-to-right shunt through the ventricular septal defect increases and eventually leads to symptoms of heart failure within the 1st mo or 2 of life.

Significant differences between the neonatal circulation and that of older infants include: (1) right-to-left or left-to-right shunting may persist across the patent foramen ovale; (2) in the presence of cardiopulmonary disease, continued patency of the ductus arteriosus may allow left-to-right, right-to-left, or bidirectional shunting; (3) the neonatal pulmonary vasculature constricts more vigorously in response to hypoxemia, hypercapnia, and acidosis; (4) the wall thickness and muscle mass of the neonatal left and right ventricles are almost equal; and (5) newborn infants at rest have relatively high oxygen consumption, which is associated with relatively high cardiac output. The newborn cardiac output (approximately 350 mL/kg/min) falls in the 1st 2 mo of life to approximately 150 mL/kg/min and then more gradually to the normal adult cardiac output of approximately 75 mL/kg/min. Although fetal hemoglobin is beneficial to delivery of oxygen in the low Po_2 fetal circulation, the high percentage of fetal hemoglobin present in the newborn may actually interfere with delivery of oxygen to tissues in the high systemic Po_2 neonatal circulation (see Chapter 101.1).

The foramen ovale is usually functionally closed by the 3rd mo of life, although it is possible to pass a probe through the overlapping flaps in a large percentage of children and in 15-25% of adults. Functional closure of the ductus arteriosus is usually complete by 10-15 hr in a normal neonate, although the ductus may remain patent much longer in the presence of congenital heart disease, especially when associated with cyanosis. In premature newborn infants, an evanescent systolic murmur with late accentuation or a continuous murmur may be audible, and in the context of respiratory distress syndrome, the presence of a patent ductus arteriosus should be suspected (see Chapter 101.3).

The normal ductus arteriosus differs morphologically from the adjoining aorta and pulmonary artery in that the ductus has a significant amount of circularly arranged smooth muscle in its medial layer. During fetal life, patency of the ductus arteriosus appears to be maintained by the combined relaxant effects of low oxygen tension and endogenously produced prostaglandins, specifically prostaglandin E_2. In a full-term neonate, oxygen is the most important factor controlling ductal closure. When the Po_2 of the blood passing through the ductus reaches about 50 mm Hg, the ductal wall begins to constrict. The effects of oxygen on ductal smooth muscle may be direct or mediated by its effects on prostaglandin synthesis. Gestational age also appears to play an important role; the ductus of a premature infant is less responsive to oxygen, even though its musculature is developed.

Section 2

Evaluation of the Cardiovascular System

Chapter 422

History and Physical Examination

Daniel Bernstein

The importance of the history and physical examination cannot be overemphasized in the evaluation of infants and children with suspected cardiovascular disorders. Patients may require further laboratory evaluation and eventual treatment, or the family may be reassured that no significant problem exists. Although the ready availability of echocardiography may entice the clinician to skip these preliminary steps, an initial evaluation by a skilled cardiologist is preferred for several reasons: (1) a cardiac examination allows the cardiologist to guide the echocardiographic evaluation toward confirming or eliminating specific diagnoses, thereby increasing its accuracy; (2) because most childhood murmurs are innocent, evaluation by a pediatric cardiologist can eliminate unnecessary and expensive laboratory tests; and (3) the cardiologist's knowledge and experience are important in reassuring the patient's family and preventing unnecessary restrictions on healthy physical activity. An experienced pediatric cardiologist can differentiate an innocent murmur from serious congenital heart disease by history and physical alone with a high sensitivity and specificity.

HISTORY

A comprehensive cardiac history starts with details of the perinatal period including the presence of cyanosis, respiratory distress, or prematurity. Maternal complications such as gestational diabetes, teratogenic medications, systemic lupus erythematosus, or substance abuse can be associated with cardiac problems. If cardiac symptoms began during infancy, the timing of the initial symptoms should be noted to provide important clues about the specific cardiac condition.

Many of the symptoms of **heart failure** in infants and children are age specific. In infants, feeding difficulties are common. Inquiry should be made about the frequency of feeding and either the volume of each feeding or the time spent on each breast. An infant with heart failure often takes less volume per feeding and becomes dyspneic or diaphoretic while sucking. After falling asleep exhausted, the baby, inadequately fed, will awaken for the next feeding after a brief time. This cycle continues around the clock and must be carefully differentiated from colic or other feeding disorders. Additional symptoms and signs include those of respiratory distress: rapid breathing, nasal flaring, cyanosis, and chest retractions. In older children, heart failure may be manifested as exercise intolerance, difficulty keeping up with peers during sports or the need for a nap after coming home from school, poor growth, or chronic abdominal complaints. Eliciting a history of fatigue in an older child requires questions about age-specific activities, including stair climbing, walking, bicycle riding, physical education class, and competitive sports; information should be obtained regarding more severe manifestations such as orthopnea and nocturnal dyspnea.

Cyanosis at rest is often overlooked by parents; it may be mistaken for a normal individual variation in color. Cyanosis during crying or exercise, however, is more often noted as abnormal by observant parents. Many infants and toddlers turn "blue around the lips" when crying vigorously or during breath-holding spells; this condition must be carefully differentiated from cyanotic heart disease by inquiring about inciting factors, the length of episodes, and whether the tongue and mucous membranes also appear cyanotic. Newborns often have cyanosis of their extremities (acrocyanosis) when undressed and cold; this response to cold must be carefully differentiated from true cyanosis, where the mucous membranes are also blue.

Chest pain is an unusual manifestation of cardiac disease in pediatric patients, although it is a frequent cause for referral to a pediatric cardiologist, especially in adolescents. Nonetheless, a careful history, physical examination, and, if indicated, laboratory or imaging tests will assist in identifying the cause of chest pain (Table 422-1). For patients with some forms of repaired congenital heart disease or those with a

Table 422-1	Differential Diagnosis of Chest Pain in Pediatric Patients
MUSCULOSKELETAL (COMMON) Trauma (accidental, abuse) Exercise, overuse injury (strain, bursitis) Costochondritis (Tietze syndrome) Herpes zoster (cutaneous) Pleurodynia Fibrositis Slipping rib Precordial catch Sickle cell anemia vasoocclusive crisis Osteomyelitis (rare) Primary or metastatic tumor (rare)	
PULMONARY (COMMON) Pneumonia Pleurisy Asthma Chronic cough Pneumothorax Infarction (sickle cell anemia) Foreign body Embolism (rare) Pulmonary hypertension (rare) Tumor (rare) Bronchiectasis	
GASTROINTESTINAL (LESS COMMON) Esophagitis (gastroesophageal reflux, infectious, pill) Esophageal foreign body Esophageal spasm Cholecystitis Subdiaphragmatic abscess Perihepatitis (Fitz-Hugh-Curtis syndrome) Peptic ulcer disease Pancreatitis	
CARDIAC (LESS COMMON) Pericarditis Postpericardiotomy syndrome Endocarditis Cardiomyopathy Mitral valve prolapse Aortic or subaortic stenosis Arrhythmias Marfan syndrome (dissecting aortic aneurysm) Kawasaki disease Cocaine, sympathomimetic ingestion Angina (familial hypercholesterolemia, anomalous coronary artery)	
IDIOPATHIC (COMMON) Anxiety, hyperventilation Panic disorder	
OTHER (LESS COMMON) Spinal cord or nerve root compression Breast-related pathologic condition (mastalgia) Castleman disease (lymph node neoplasm)	

history of Kawasaki disease (see Chapter 444.1), however, chest pain should be evaluated carefully for a coronary etiology.

Cardiac disease may be a manifestation of a known congenital malformation syndrome with typical physical findings (Table 422-2) or a manifestation of a generalized disorder affecting the heart and other organ systems (Table 422-3). Extracardiac malformations may be noted in 20-45% of infants with congenital heart disease. Between 5% and 10% of patients have a known chromosomal abnormality; the importance of genetic evaluation will increase as our knowledge of specific gene defects linked to congenital heart disease increases.

A careful family history may also reveal early (at age <50 yr) coronary artery disease or stroke (suggestive of familial hypercholesterolemia or thrombophilia), sudden death (suggestive of cardiomyopathy or familial arrhythmic disorder), generalized muscle disease (suggestive of 1 of the muscular dystrophies, dermatomyositis, or familial or metabolic cardiomyopathy), or 1st-degree relatives with congenital heart disease.

GENERAL PHYSICAL EXAMINATION

A general assessment of the patient is always the first part of the examination, with specific attention directed toward the presence of cyanosis, abnormalities in growth, chest wall abnormalities, and any evidence of respiratory distress. Although the murmur may be the most prominent part of the overall examination, any murmur must be placed in context of other physical findings. Frequently, associated findings, such as the quality of the pulses, the presence of a ventricular heave or thrill, or the splitting of the second heart sound, provide important clues to a specific cardiac diagnosis.

Accurate measurement of height and weight and plotting on a standard growth chart are important because both cardiac failure and chronic cyanosis can result in **failure to thrive.** Growth failure is manifested predominantly by poor weight gain; if length or head circumference is also affected, additional congenital malformations or metabolic disorders should be suspected.

Mild cyanosis may be too subtle for early detection, and clubbing of the fingers and toes is not usually manifested until late in the 1st yr of life, even in the presence of severe arterial oxygen desaturation. **Cyanosis** is best observed over the nail beds, lips, tongue, and mucous membranes. Differential cyanosis, manifested as blue lower extremities and pink upper extremities (usually the right arm), is seen with right-to-left shunting across a ductus arteriosus in the presence of coarctation or an interrupted aortic arch. Circumoral cyanosis or blueness around the forehead may be the result of prominent venous plexuses in these areas, rather than decreased arterial oxygen saturation. The extremities of infants often turn blue when the infant is unwrapped and cold (acrocyanosis), and this condition can be distinguished from central cyanosis by examination of the tongue and mucous membranes.

Heart failure in infants and children usually results in some degree of hepatomegaly and occasionally splenomegaly. The sites of **peripheral** edema are age dependent. In infants, edema is usually seen around the eyes and over the flanks, especially on initially waking. Older children and teenagers manifest both periorbital edema and pedal edema. A not uncommon initial complaint in these older patients is that their clothes no longer fit.

The heart rate of newborn infants is rapid and subject to wide fluctuations (Table 422-4). The average rate ranges from 120-140 beats/min and may increase to 170+ beats/min during crying and activity or drop to 70-90 beats/min during sleep. As the child grows older, the average pulse rate decreases and may be as low as 40 beats/min at rest in athletic adolescents. Persistent tachycardia (>200 beats/min in neonates, 150 beats/min in infants, or 120 beats/min in older children), bradycardia, or an irregular heartbeat other than sinus arrhythmia requires investigation to exclude pathologic arrhythmias (see Chapter 435). Sinus arrhythmia can usually be distinguished by the rhythmic nature of the heart rate variations, occurring in concert with the respiratory cycle, and with a P wave before every QRS complex.

Careful evaluation of the character of the **pulses** is an important early step in the physical diagnosis of congenital heart disease. A wide pulse pressure with bounding pulses may suggest an aortic runoff lesion such as patent ductus arteriosus, aortic insufficiency, an arterial-venous communication, or increased cardiac output secondary to anemia, anxiety, or conditions associated with increased catecholamine or thyroid hormone secretion. The presence of diminished pulses in all extremities is associated with pericardial tamponade, left ventricular outflow obstruction, or cardiomyopathy. The radial and femoral pulses should always be palpated simultaneously. Normally, the femoral pulse should be appreciated immediately before the radial pulse. In infants with coarctation of the aorta, the femoral pulses may be decreased. However, in older children with coarctation of the aorta, blood flow to the descending aorta may channel through collateral vessels and results in the femoral pulse being palpable but delayed until after the radial pulse **(radial-femoral delay).**

Blood pressure should be measured in the legs as well as in the arms to be certain that coarctation of the aorta is not overlooked. Palpation of the femoral or dorsalis pedis pulse, or both, is not reliable alone to exclude coarctation. In older children, a mercury sphygmomanometer with a cuff that covers approximately two-thirds of the upper part of the arm or leg may be used for blood pressure measurement. A cuff that is too small results in falsely high readings, whereas a cuff that is too large records slightly decreased pressure. Pediatric clinical facilities should be equipped with 3, 5, 7, 12, and 18 cm cuffs to accommodate the large spectrum of pediatric patient sizes. The 1st Korotkoff sounds indicate systolic pressure. As cuff pressure is slowly decreased, the sounds usually become muffled before they disappear. Diastolic pressure may be recorded when the sounds become muffled (preferred) or when they disappear altogether; the former is usually slightly higher and the latter slightly lower than true diastolic pressure. For lower-extremity blood pressure determination, the stethoscope is placed over the popliteal artery. Ordinarily, the pressure recorded in the legs with the cuff technique is approximately 10 mm Hg higher than that in the arms.

In infants, blood pressure can be determined by auscultation, palpation, or an oscillometric (Dinamap) device that, when properly used, provides accurate measurements in infants as well as older children.

Blood pressure varies with the age of the child and is closely related to height and weight. Significant increases occur during adolescence, and many temporary variations take place before the more stable levels of adult life are attained. Exercise, excitement, coughing, crying, and struggling may raise the systolic pressure of infants and children as much as 40-50 mm Hg greater than their usual levels. Variability in blood pressure in children of approximately the same age and body build should be expected, and serial measurements should always be obtained when evaluating a patient with hypertension (Figs. 422-1 and 422-2).

Although of little use in infants, in cooperative older children, inspection of the **jugular venous pulse** wave provides information about central venous and right atrial pressure. The neck veins should be inspected with the patient sitting at a 90-degree angle. The external jugular vein should not be visible above the clavicles unless central venous pressure is elevated. Increased venous pressure transmitted to the internal jugular vein may appear as venous pulsations without visible distention; such pulsation is not seen in normal children reclining at an angle of 45 degrees. Because the great veins are in direct communication with the right atrium, changes in pressure and the volume of this chamber are also transmitted to the veins. The 1 exception occurs in superior vena cava obstruction, in which venous pulsatility is lost.

CARDIAC EXAMINATION

The heart should be examined in a systematic manner, starting with inspection and palpation. A **precordial bulge** to the left of the sternum with increased precordial activity suggests cardiac enlargement; such bulges can often best be appreciated by having the child lay supine with the examiner looking up from the child's feet. A **substernal thrust** indicates the presence of right ventricular enlargement, whereas an apical heave is noted with left ventricular enlargement. A hyperdynamic precordium suggests a volume load such as that found with a large left-to-right shunt, although it may be normal in a thin patient.

Table 422-2 Congenital Malformation Syndromes Associated with Congenital Heart Disease

SYNDROME	FEATURES
CHROMOSOMAL DISORDERS	
Trisomy 21 (Down syndrome)	Endocardial cushion defect, VSD, ASD
Trisomy 21p (cat eye syndrome)	Miscellaneous, total anomalous pulmonary venous return
Trisomy 18	VSD, ASD, PDA, coarctation of aorta, bicuspid aortic or pulmonary valve
Trisomy 13	VSD, ASD, PDA, coarctation of aorta, bicuspid aortic or pulmonary valve
Trisomy 9	Miscellaneous
XXXXY	PDA, ASD
Penta X	PDA, VSD
Triploidy	VSD, ASD, PDA
XO (Turner syndrome)	Bicuspid aortic valve, coarctation of aorta
Fragile X	Mitral valve prolapse, aortic root dilatation
Duplication 3q2	Miscellaneous
Deletion 4p	VSD, PDA, aortic stenosis
Deletion 9p	Miscellaneous
Deletion 5p (cri du chat syndrome)	VSD, PDA, ASD
Deletion 10q	VSD, TOF, conotruncal lesions*
Deletion 13q	VSD
Deletion 18q	VSD
SYNDROME COMPLEXES	
CHARGE association (*c*oloboma, *h*eart, *a*tresia choanae, *r*etardation, *g*enital, and *e*ar anomalies)	VSD, ASD, PDA, TOF, endocardial cushion defect
DiGeorge sequence, CATCH 22 (*c*ardiac defects, *a*bnormal facies, *t*hymic aplasia, *c*left palate, and *h*ypocalcemia)	Aortic arch anomalies, conotruncal anomalies
Alagille syndrome (arteriohepatic dysplasia)	Peripheral pulmonic stenosis, PS, TOF
VATER association (*v*ertebral, *a*nal, *t*racheo*e*sophageal, *r*adial, and *r*enal anomalies)	VSD, TOF, ASD, PDA
FAVS (*f*acio*a*uriculo*v*ertebral *s*pectrum)	TOF, VSD
CHILD (congenital hemidysplasia with ichthyosiform erythroderma, limb defects)	Miscellaneous
Mulibrey nanism (muscle, liver, brain, eye)	Pericardial thickening, constrictive pericarditis
Asplenia syndrome	Complex cyanotic heart lesions with decreased pulmonary blood flow, transposition of great arteries, anomalous pulmonary venous return, dextrocardia, single ventricle, single atrioventricular valve
Polysplenia syndrome	Acyanotic lesions with increased pulmonary blood flow, azygos continuation of inferior vena cava, partial anomalous pulmonary venous return, dextrocardia, single ventricle, common atrioventricular valve
PHACE syndrome (*p*osterior brain fossa anomalies, facial *h*emangiomas, *a*rterial anomalies, *c*ardiac anomalies and aortic coarctation, *e*ye anomalies)	VSD, PDA, coarctation of aorta, arterial aneurysms
TERATOGENIC AGENTS	
Congenital rubella	PDA, peripheral pulmonic stenosis
Fetal hydantoin syndrome	VSD, ASD, coarctation of aorta, PDA
Fetal alcohol syndrome	ASD, VSD
Fetal valproate effects	Coarctation of aorta, hypoplastic left side of heart, aortic stenosis, pulmonary atresia, VSD
Maternal phenylketonuria	VSD, ASD, PDA, coarctation of aorta
Retinoic acid embryopathy	Conotruncal anomalies
OTHERS	
Apert syndrome	VSD
Autosomal dominant polycystic kidney disease	Mitral valve prolapse
Carpenter syndrome	PDA
Conradi syndrome	VSD, PDA
Crouzon disease	PDA, coarctation of aorta
Cutis laxa	Pulmonary hypertension, pulmonic stenosis
de Lange syndrome	VSD
Ellis–van Creveld syndrome	Single atrium, VSD
Holt-Oram syndrome	ASD, VSD, 1st-degree heart block
Infant of diabetic mother	Hypertrophic cardiomyopathy, VSD, conotruncal anomalies
Kartagener syndrome	Dextrocardia
Meckel-Gruber syndrome	ASD, VSD
Noonan syndrome	Pulmonic stenosis, ASD, cardiomyopathy
Pallister-Hall syndrome	Endocardial cushion defect
Rubinstein-Taybi syndrome	VSD
Scimitar syndrome	Hypoplasia of right lung, anomalous pulmonary venous return to inferior vena cava
Smith-Lemli-Opitz syndrome	VSD, PDA
TAR syndrome (thrombocytopenia and absent radius)	ASD, TOF
Treacher Collins syndrome	VSD, ASD, PDA
Williams syndrome	Supravalvular aortic stenosis, peripheral pulmonic stenosis

ASD, atrial septal defect; AV, aortic valve; PDA, patent ductus arteriosus; PS, pulmonary stenosis; TOF, tetralogy of Fallot; VSD, ventricular septal defect.
*Conotruncal includes TOF, pulmonary atresia, truncus arteriosus, and transposition of great arteries.

Table 422-3 Cardiac Manifestations of Systemic Diseases

SYSTEMIC DISEASE	CARDIAC COMPLICATIONS
INFLAMMATORY DISORDERS	
Sepsis	Hypotension, myocardial dysfunction, pericardial effusion, pulmonary hypertension
Juvenile idiopathic arthritis	Pericarditis, rarely myocarditis
Systemic lupus erythematosus	Pericarditis, Libman-Sacks endocarditis, coronary arteritis, coronary atherosclerosis (with steroids), congenital heart block
Scleroderma	Pulmonary hypertension, myocardial fibrosis, cardiomyopathy
Dermatomyositis	Cardiomyopathy, arrhythmias, heart block
Kawasaki disease	Coronary artery aneurysm and thrombosis, myocardial infarction, myocarditis, valvular insufficiency
Sarcoidosis	Granuloma, fibrosis, amyloidosis, biventricular hypertrophy, arrhythmias
Lyme disease	Arrhythmias, myocarditis
Löffler hypereosinophilic syndrome	Endomyocardial disease
INBORN ERRORS OF METABOLISM	
Refsum disease	Arrhythmia, sudden death
Hunter or Hurler syndrome	Valvular insufficiency, heart failure, hypertension
Fabry disease	Mitral insufficiency, coronary artery disease with myocardial infarction
Glycogen storage disease IIa (Pompe disease)	Short P-R interval, cardiomegaly, heart failure, arrhythmias
Carnitine deficiency	Heart failure, cardiomyopathy
Gaucher disease	Pericarditis
Homocystinuria	Coronary thrombosis
Alkaptonuria	Atherosclerosis, valvular disease
Morquio-Ullrich syndrome	Aortic incompetence
Scheie syndrome	Aortic incompetence
CONNECTIVE TISSUE DISORDERS	
Arterial calcification of infancy	Calcinosis of coronary arteries, aorta
Marfan syndrome	Aortic and mitral insufficiency, dissecting aortic aneurysm, mitral valve prolapse
Congenital contractural arachnodactyly	Mitral insufficiency or prolapse
Ehlers-Danlos syndrome	Mitral valve prolapse, dilatated aortic root
Osteogenesis imperfecta	Aortic incompetence
Pseudoxanthoma elasticum	Peripheral arterial disease
NEUROMUSCULAR DISORDERS	
Friedreich ataxia	Cardiomyopathy
Duchenne dystrophy	Cardiomyopathy, heart failure
Tuberous sclerosis	Cardiac rhabdomyoma
Familial deafness	Occasionally arrhythmia, sudden death
Neurofibromatosis	Pulmonic stenosis, pheochromocytoma, coarctation of aorta
Riley-Day syndrome	Episodic hypertension, postural hypotension
Von Hippel–Lindau disease	Hemangiomas, pheochromocytomas
ENDOCRINE-METABOLIC DISORDERS	
Graves disease	Tachycardia, arrhythmias, heart failure
Hypothyroidism	Bradycardia, pericardial effusion, cardiomyopathy, low-voltage electrocardiogram
Pheochromocytoma	Hypertension, myocardial ischemia, myocardial fibrosis, cardiomyopathy
Carcinoid	Right-sided endocardial fibrosis
HEMATOLOGIC DISORDERS	
Sickle cell anemia	High-output heart failure, cardiomyopathy, pulmonary hypertension
Thalassemia major	High-output heart failure, hemochromatosis
Hemochromatosis (1° or 2°)	Cardiomyopathy
OTHERS	
Appetite suppressants (fenfluramine and dexfenfluramine)	Cardiac valvulopathy, pulmonary hypertension
Cockayne syndrome	Atherosclerosis
Familial dwarfism and nevi	Cardiomyopathy
Jervell and Lange-Nielsen syndrome	Prolonged QT interval, sudden death
Kearns-Sayre syndrome	Heart block
LEOPARD syndrome (lentiginosis)	Pulmonic stenosis, prolonged Q-T interval
Progeria	Accelerated atherosclerosis
Osler-Weber-Rendu disease	Arteriovenous fistula (lung, liver, mucous membrane)
Romano-Ward syndrome	Prolonged Q-T interval, sudden death
Weill-Marchesani syndrome	Patent ductus arteriosus
Werner syndrome	Vascular sclerosis, cardiomyopathy

LEOPARD, multiple *l*entigines, *e*lectrocardiographic conduction abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormal genitals, *r*etardation of growth, sensorineural *d*eafness.

Table 422-4 Pulse Rates at Rest

AGE	LOWER LIMITS OF NORMAL (beats/min)		AVERAGE (beats/min)		UPPER LIMITS OF NORMAL (beats/min)	
Newborn	70		125		190	
1–11 mo	80		120		160	
2 yr	80		110		130	
4 yr	80		100		120	
6 yr	75		100		115	
8 yr	70		90		110	
10 yr	70		90		110	
	GIRLS	BOYS	GIRLS	BOYS	GIRLS	BOYS
12 yr	70	65	90	85	110	105
14 yr	65	60	85	80	105	100
16 yr	60	55	80	75	100	95
18 yr	55	50	75	70	95	90

An overly silent precordium with a barely detectable apical impulse suggests pericardial effusion or severe cardiomyopathy but may be normal in an obese patient.

The relationship of the **apical impulse** to the midclavicular line is also helpful in the estimation of cardiac size: the apical impulse moves laterally and inferiorly with enlargement of the left ventricle. Right-sided apical impulses signify dextrocardia, tension pneumothorax, or left-sided thoracic space-occupying lesions (e.g., diaphragmatic hernia).

Thrills are the palpable equivalent of murmurs and correlate with the area of maximal auscultatory intensity of the murmur. It is important to palpate the suprasternal notch and neck for aortic bruits, which may indicate the presence of aortic stenosis or, when faint, pulmonary stenosis. Right lower sternal border and apical systolic thrills are characteristic of ventricular septal defect and mitral insufficiency, respectively. Diastolic thrills are occasionally palpable in the presence of atrioventricular valve stenosis. The timing and localization of thrills should be carefully noted.

Auscultation is an art that improves with practice. The diaphragm of the stethoscope is placed firmly on the chest for high-pitched sounds; a lightly placed bell is optimal for low-pitched sounds. The physician should initially concentrate on the characteristics of the individual heart sounds and their variation with respirations and later concentrate on murmurs. The patient should be supine, lying quietly, and breathing normally. The **1st heart sound** is best heard at the apex, whereas the **2nd heart sound** should be evaluated at the upper left and right sternal borders. The 1st heart sound is caused by closure of the atrioventricular valves (mitral and tricuspid); the 2nd sound is caused by closure of the semilunar valves (aortic and pulmonary) (Fig. 422-3). During inspiration, the decrease in intrathoracic pressure results in increased filling of the right side of the heart, which leads to an increased right ventricular ejection time and thus delayed closure of the pulmonary valve; consequently, **splitting of the 2nd heart sound** increases during inspiration and decreases during expiration.

Often, the 2nd heart sound seems to be single during expiration. The presence of a normally split 2nd sound is strong evidence against the diagnosis of atrial septal defect, defects associated with pulmonary arterial hypertension, severe pulmonary valve stenosis, aortic and pulmonary atresia, and truncus arteriosus. Wide splitting is noted in atrial septal defect, pulmonary stenosis, Ebstein anomaly, total anomalous pulmonary venous return, and right bundle branch block. An accentuated pulmonic component of the 2nd sound with narrow splitting is a sign of pulmonary hypertension. A single 2nd sound occurs in pulmonary or aortic atresia or severe stenosis, truncus arteriosus, and, often, transposition of the great arteries.

A **3rd heart sound** is best heard with the bell at the apex in mid-diastole. A **4th sound** occurring in conjunction with atrial contraction may be heard just before the 1st heart sound in late diastole. The 3rd sound may be normal in an adolescent with a relatively slow heart rate, but in a patient with the clinical signs of heart failure and tachycardia, it may be heard as a gallop rhythm and may merge with a 4th heart sound, a finding known as a summation gallop. A gallop rhythm is attributed to poor compliance of the ventricle, and exaggeration of the normal 3rd sound is associated with ventricular filling.

Ejection clicks, which are heard in early systole, are usually caused by a mildly to moderately stenotic aortic or pulmonary valve or to a dilated ascending aorta or pulmonary artery. They are heard so close to the 1st heart sound that they may be mistaken for a split 1st sound. Aortic ejection clicks are best heard at the left middle to right upper sternal border and are constant in intensity. They occur in conditions in which the aortic valve is stenotic or the aorta is dilated (tetralogy of Fallot, truncus arteriosus). Pulmonary ejection clicks, which are associated with mild to moderate pulmonary stenosis, are best heard at the left middle to upper sternal border and vary with respirations, often disappearing with inspiration. Split 1st heart sounds are usually heard best at the lower left sternal border. A midsystolic click heard at the apex, often preceding a late systolic murmur, suggests mitral valve prolapse.

Murmurs should be described according to their intensity, pitch, timing (systolic or diastolic), variation in intensity, time to peak intensity, area of maximal intensity, and radiation to other areas. Auscultation for murmurs should be carried out across the upper precordium, down the left or right sternal border, and out to the apex and left axilla. Auscultation should also always be performed in the right axilla and over both sides of the back. Systolic murmurs are classified as ejection, pansystolic, or late systolic according to the timing of the murmur in relation to the 1st and 2nd heart sounds. The intensity of systolic murmurs is graded from I to VI: I, barely audible; II, medium intensity; III, loud but no thrill; IV, loud with a thrill; V, very loud but still requiring positioning of the stethoscope at least partly on the chest; and VI, so loud that the murmur can be heard with the stethoscope off the chest. In patients who have undergone prior heart surgery, a murmur of grade IV or greater may be heard in the absence of a thrill.

Systolic ejection murmurs start a short time after a well-heard 1st heart sound, increase in intensity, peak, and then decrease in intensity; they usually end before the 2nd sound. In patients with severe pulmonary stenosis, however, the murmur may extend beyond the 1st component of the 2nd sound, thus obscuring it. **Pansystolic or holosystolic murmurs** begin almost simultaneously with the 1st heart sound and continue throughout systole, on occasion becoming gradually decrescendo. It is helpful to remember that after closure of the atrioventricular valves (the 1st heart sound), a brief period occurs during which ventricular pressure increases but the semilunar valves remain closed (isovolumic contraction; see Fig. 422-3). Thus, pansystolic murmurs (heard during both isovolumic contraction and the ejection phases of systole) cannot be caused by flow across the semilunar valves because these valves are closed during isovolumic contraction. Pansystolic murmurs must therefore be related to blood exiting the contracting ventricle via either an abnormal opening (a ventricular septal defect) or atrioventricular (mitral or tricuspid) valve insufficiency. Systolic ejection murmurs usually imply increased flow or stenosis across one of the ventricular outflow tracts (aortic or pulmonic). In infants with rapid heart rates, it is often difficult to distinguish between ejection and pansystolic murmurs. If a clear and distinct 1st heart sound can be appreciated, the murmur is most likely ejection in nature.

A **continuous murmur** is a systolic murmur that continues or "spills" into diastole and indicates continuous flow, such as in the presence of a patent ductus arteriosus or other aortopulmonary communication. This murmur should be differentiated from a to-and-fro murmur, where the systolic component of the murmur ends at or before the 2nd sound and the diastolic murmur begins after semilunar valve closure (aortic or pulmonary stenosis combined with insufficiency). A late systolic murmur begins well beyond the 1st heart sound and continues until the end of systole. Such murmurs may be heard

after a midsystolic click in patients with mitral valve prolapse and insufficiency.

Several types of **diastolic murmurs** (graded I-IV) can be identified. A decrescendo diastolic murmur is a blowing murmur along the left sternal border that begins with S_2 and diminishes toward mid-diastole. When high-pitched, this murmur is associated with aortic valve insufficiency or pulmonary insufficiency related to pulmonary hypertension. When low-pitched, this murmur is associated with pulmonary valve insufficiency in the absence of pulmonary hypertension. A low-pitched decrescendo diastolic murmur is typically noted after surgical repair of the pulmonary outflow tract in defects such as tetralogy of Fallot or in patients with absent pulmonary valves. A rumbling mid-diastolic murmur at the left middle and lower sternal border may be due to increased blood flow across the tricuspid valve, such as occurs with an atrial septal defect or, less often, because of actual stenosis of this valve. When this murmur is heard at the apex, it is caused by increased flow across the mitral valve, such as occurs with large left-to-right shunts at the ventricular level (ventricular septal defects), at the great vessel level (patent ductus arteriosus, aortopulmonary shunts), or with increased flow because of mitral insufficiency. When an apical diastolic rumbling murmur is longer and is accentuated at the end of diastole (presystolic), it usually indicates anatomic mitral valve stenosis.

The absence of a precordial murmur does not rule out significant congenital or acquired heart disease. Congenital heart defects, some of which are ductal dependent, may not demonstrate a murmur if the ductus arteriosus closes. These lesions include pulmonary or tricuspid valve atresia and transposition of the great arteries. Murmurs may seem insignificant in patients with severe aortic stenosis, atrial septal defects, anomalous pulmonary venous return, atrioventricular septal defects, coarctation of the aorta, or anomalous insertion of a coronary artery. Careful attention to other components of the physical examination (growth failure, cyanosis, peripheral pulses, precordial impulse, heart sounds) increases the index of suspicion of congenital heart defects in these cases. In contrast, loud murmurs may be present in the absence of structural heart disease, for example, in patients with a large noncardiac arteriovenous malformation, myocarditis, severe anemia, or hypertension.

Many murmurs are not associated with significant hemodynamic abnormalities. These murmurs are referred to as functional, normal, insignificant, or innocent (the preferred term). During routine random auscultation, more than 30% of children may have an innocent murmur at one time in their lives; this percentage increases when auscultation is carried out under nonbasal circumstances (high cardiac output because of fever, infection, anxiety). The most **common innocent murmur** is a medium-pitched, vibratory or "musical," relatively short systolic ejection murmur, which is heard best along the left lower and midsternal border and has no significant radiation to the apex, base, or back. It is heard most frequently in children between 3 and 7 yr of age. The intensity of the murmur often changes with respiration and position and may be attenuated in the sitting or prone position. Innocent pulmonic murmurs are also common in children and adolescents and originate from normal turbulence during ejection into the pulmonary artery. They are higher pitched, blowing, brief early systolic murmurs of grades I-II in intensity and are best detected in the 2nd left parasternal space with the patient in the supine position. Features suggestive of heart disease include murmurs that are pansystolic, grade III or higher, harsh, located at the left upper sternal border, and associated with an early or midsystolic click or an abnormal 2nd heart sound.

A **venous hum** is another example of a common innocent murmur heard during childhood. Such hums are produced by turbulence of blood in the jugular venous system; they have no pathologic significance and may be heard in the neck or anterior portion of the upper part of the chest. A venous hum consists of a soft humming sound

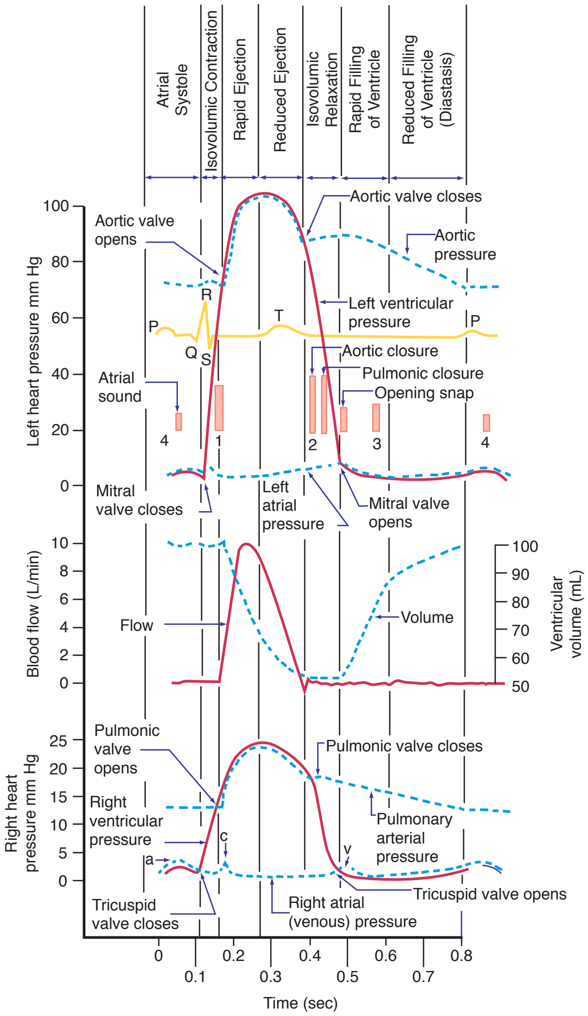

Figure 422-3 Idealized diagram of the temporal events of a cardiac cycle.

heard in both systole and diastole; it can be exaggerated or made to disappear by varying the position of the head, or it can be decreased by lightly compressing the jugular venous system in the neck. These simple maneuvers are sufficient to differentiate a venous hum from the murmurs produced by organic cardiovascular disease, particularly a patent ductus arteriosus.

The lack of significance of an innocent murmur should be discussed with the child's parents. It is important to offer complete reassurance because lingering doubts about the importance of a cardiac murmur may have profound effects on child-rearing practices, most often in the form of overprotectiveness. An underlying fear that a cardiac abnormality is present may negatively affect a child's self-image and subtly influence personality development. The physician should explain that an innocent murmur is simply a "noise" and does not indicate the presence of a significant cardiac defect. When asked, "Will it go away?," the best response is to state that because the murmur has no clinical significance, it does not matter whether it "goes away." Parents should be warned that the intensity of the murmur might increase during febrile illnesses, a time when, typically, another physician examines the child. With growth, however, innocent murmurs are less well heard and often disappear completely. At times, additional studies may be indicated to rule out a congenital heart defect, but "routine" electrocardiographic, chest roentgenographic, and echocardiographic examinations should be avoided in well children with innocent murmurs.

Chapter 423

Laboratory Evaluation

423.1 Radiologic Assessment

Daniel Bernstein

The chest x-ray remains a highly valuable diagnostic tool and is often the first imaging study performed in a child suspected of having a cardiac defect. It can provide information about cardiac size and shape, pulmonary blood flow (vascularity), pulmonary edema, and associated lung and thoracic anomalies that may be associated with congenital syndromes (skeletal dysplasias, extra or deficient number of ribs, abnormal vertebrae, previous cardiac surgery).

The most frequently used measurement of cardiac size is the maximal width of the cardiac shadow in a posteroanterior chest film taken mid-inspiration. A vertical line is drawn down the middle of the sternal shadow, and perpendicular lines are drawn from the sternal line to the extreme right and left borders of the heart; the sum of the lengths of these lines is the maximal cardiac width. The maximal chest width is obtained by drawing a horizontal line between the right and left inner borders of the rib cage at the level of the top of the right diaphragm. When the maximal cardiac width is more than half the maximal chest width (cardiothoracic ratio >50%), the heart is usually enlarged. Cardiac size should be evaluated only when the film is taken during inspiration with the patient in an upright position. A diagnosis of "cardiac enlargement" on expiratory or prone films is a common cause of unnecessary referrals and laboratory studies.

The cardiothoracic ratio is a less useful index of cardiac enlargement in infants than in older children because the horizontal position of the heart may increase the ratio to >50% in the absence of true enlargement. Furthermore, the thymus may overlap not only the base of the heart but also virtually the entire mediastinum, thus obscuring the true cardiac silhouette.

A lateral chest roentgenogram may be helpful in infants as well as in older children with pectus excavatum or other conditions that result in a narrow anteroposterior chest dimension. In these situations, the heart may appear small in the lateral view and suggest that the apparent enlargement in the posteroanterior projection was due to either the thymic image (anterior mediastinum only) or flattening of the cardiac chambers as a result of a structural chest abnormality.

In the posteroanterior view, the left border of the cardiac shadow consists of 3 convex shadows produced, from above downward, by the aortic knob, the main and left pulmonary arteries, and the left ventricle (Fig. 423-1). In cases of moderate to marked left atrial enlargement, the atrium may project between the pulmonary artery and the left ventricle. The outflow tract of the right ventricle does not contribute to the shadows formed by the left border of the heart. The aortic knob is not as easily seen in infants and children as in adults. The side of the aortic arch (left or right) can often be inferred as being opposite the side of the midline from which the air-filled trachea is visualized. This observation is important because a right-sided aortic arch is often present in cyanotic congenital heart disease, particularly in tetralogy of Fallot. Three structures contribute to the right border of the cardiac silhouette. In the view from above, they are the superior vena cava, the ascending aorta, and the right atrium.

Enlargement of cardiac chambers or major arteries and veins results in prominence of the areas in which these structures are normally outlined on the chest x-ray. In contrast, the electrocardiogram (ECG) is a more sensitive and accurate index of **ventricular hypertrophy.**

The chest roentgenogram is also an important tool for assessing the degree of pulmonary vascularity. Pulmonary overcirculation is usually

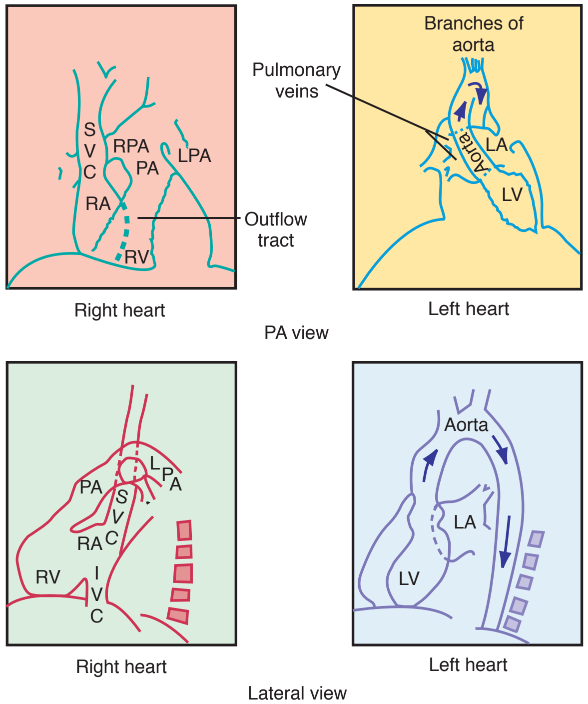

Figure 423-1 **Idealized diagrams showing normal position of the cardiac chambers and great blood vessels.** IVC, inferior vena cava; LA, left atrium; LPA, left pulmonary artery; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava. *(Adapted and redrawn from Dotter CT, Steinberg I: Angiocardiographic interpretation, Radiology 153:513, 1949.)*

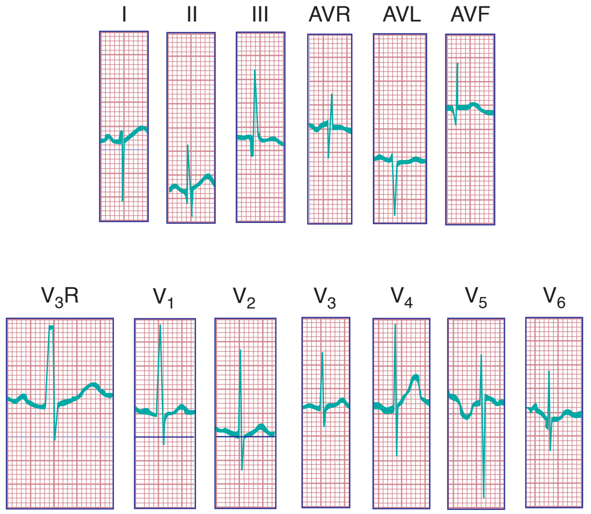

Figure 423-2 Electrocardiogram in a normal neonate <24 hr of age. Note the dominant R wave and upright T waves in leads V_3R and V_1 (V_3R paper speed = 50 mm/sec).

associated with left-to-right shunt lesions, whereas pulmonary undercirculation is associated with obstruction of the outflow tract of the right ventricle. The esophagus is closely related to the great vessels, and a barium esophagogram can help delineate these structures in the initial evaluation of suspected vascular rings, although this has largely been supplanted by CT. Echocardiographic examination best defines the morphologic features of intracardiac chambers, cardiac valves, and intracardiac shunts. CT is used as an adjunct to echo to evaluate extracardiac vascular morphology. MRI is used to quantitate ventricular volumes, cardiac function, and shunt and regurgitant fractions.

423.2 Electrocardiography

Daniel Bernstein

DEVELOPMENTAL CHANGES

The marked changes that occur in cardiac physiology and chamber dominance during the perinatal transition (see Chapter 421) are reflected in the evolution of the ECG during the neonatal period. Because vascular resistance in the pulmonary and systemic circulations is nearly equal in a term fetus, the intrauterine work of the heart results in an equal mass of both the right and left ventricles. After birth, systemic vascular resistance rises when the placental circulation is eliminated, and pulmonary vascular resistance falls when the lungs expand. These changes are reflected in the ECG as the right ventricular wall begins to thin.

The ECG demonstrates these anatomic and hemodynamic features principally by changes in QRS and T-wave morphologic features. Commonly, a 13-lead ECG is performed in pediatric patients, including either lead V_3R or V_4R, which are important in the evaluation of right ventricular hypertrophy. On occasion, lead V_1 is positioned too far leftward to reflect right ventricular forces accurately. This problem is present particularly in premature infants, in whom the electrocardiographic electrode gel may produce contact among all the precordial leads.

During the 1st days of life, right axis deviation, large R waves, and upright T waves in the right precordial leads (V_3R or V_4R and V_1) are the norm (Fig. 423-2). As pulmonary vascular resistance decreases in the 1st few days after birth, the right precordial T waves become negative. In the great majority of instances, this change occurs within the 1st 48 hr of life. Upright T waves that persist in leads V_3R, V_4R, or V_1 beyond 1 wk of life are an abnormal finding indicating right ventricular hypertrophy or strain, even in the absence of QRS voltage criteria. The T wave in V_1 should never be positive before 6 yr of age and may remain negative into adolescence. This finding represents one of the most important, yet subtle differences between pediatric and adult ECGs and is a common source of error when adult cardiologists interpret pediatric ECGs.

In a newborn, the mean **QRS frontal-plane axis** normally lies in the range of +110 to +180 degrees. The right-sided chest leads reveal a larger positive (R) than negative (S) wave and may do so for months because the right ventricle remains relatively thick throughout infancy. Left-sided leads (V_5 and V_6) also reflect right-sided dominance in the early neonatal period, when the R : S ratio in these leads may be <1. A dominant R wave in V_5 and V_6, reflecting left ventricular forces, quickly becomes evident within the 1st few days of life (Fig. 423-3). Over the years, the QRS axis gradually shifts leftward, and the right ventricular forces slowly regress. Leads V_1, V_3R, and V_4R display a prominent R wave until 6 mo to 8 yr of age. Most children have an R : S ratio >1 in lead V_4R until they are 4 yr of age. The T waves are inverted in leads V_4R, V_1, V_2, and V_3 during infancy and may remain so into the middle of the 2nd decade of life and beyond. The processes of right ventricular thinning and left ventricular growth are best reflected in the QRS-T pattern over the right precordial leads. The diagnosis of right or left ventricular hypertrophy in a pediatric patient can be made only with an understanding of the normal developmental physiology of these chambers at various ages until adulthood is reached. As the left ventricle becomes dominant, the ECG evolves to the characteristic pattern of older children (Fig. 423-4) and adults (Fig. 423-5).

Ventricular hypertrophy may result in increased voltage in the R and S waves in the chest leads. The height of these deflections is governed by the proximity of the specific electrode to the surface of the heart; by the sequence of electrical activation through the ventricles, which can result in variable degrees of cancellation of forces; and by hypertrophy of the myocardium. Because the chest wall in infants and children, as

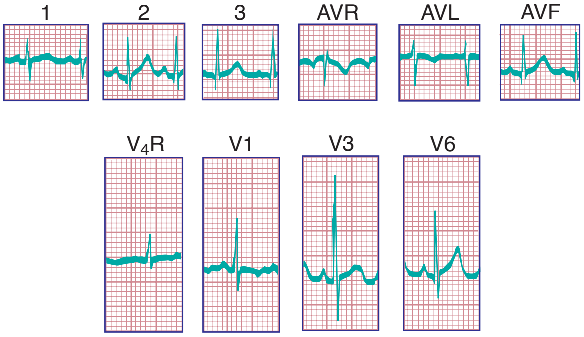

Figure 423-3 **Electrocardiogram of a normal infant.** Note the tall R and small S waves in V_4R and V_1 and the inverted T wave in these leads. A dominant R wave is also present in V_6.

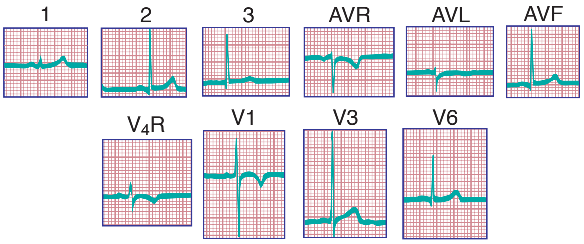

Figure 423-4 **Electrocardiogram of a normal child.** Note the relatively tall R waves and inversion of the T waves in V_4R and V_1.

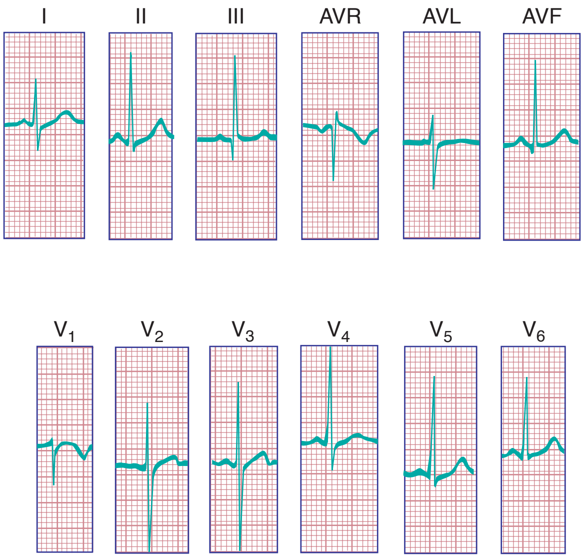

Figure 423-5 **Normal adult electrocardiogram.** Note the dominant S wave in lead V_1. This pattern in an infant would indicate the presence of left ventricular hypertrophy.

well as in adolescents, may be relatively thin, the diagnosis of ventricular hypertrophy should not be based on voltage changes alone.

The diagnosis of pathologic right ventricular hypertrophy is difficult in the 1st wk of life because physiologic right ventricular hypertrophy is a normal finding. Serial tracings are often necessary to determine whether marked right axis deviation and potentially abnormal right precordial forces or T waves, or both, will persist beyond the neonatal period (Fig. 423-6). In contrast, an adult electrocardiographic pattern

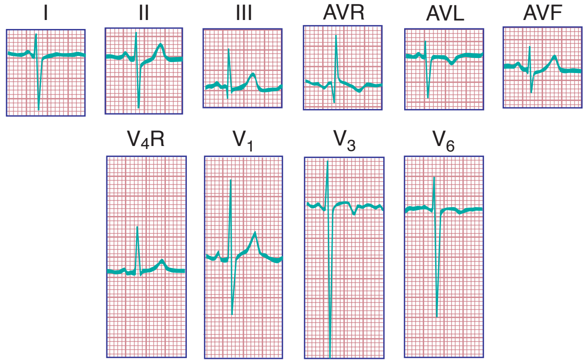

Figure 423-6 **Electrocardiogram of an infant with right ventricular hypertrophy (tetralogy of Fallot).** Note the tall R waves in the right precordium and deep S waves in V_6. The positive T waves in V_4R and V_1 are also characteristic of right ventricular hypertrophy.

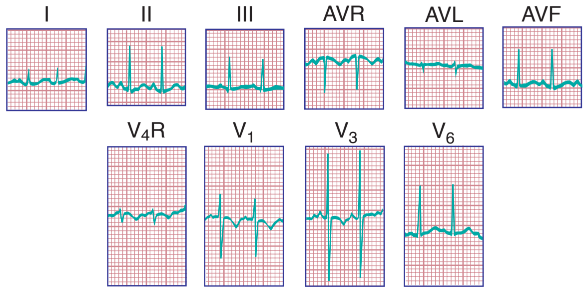

Figure 423-7 **Electrocardiogram of a premature infant (weight 2 kg and age 5 wk at the time of the tracing).** The cardiovascular system was clinically normal. Left ventricular dominance is manifested by R-wave progression across the chest, similar to tracings obtained from older children. Compare with the tracing from a normal full-term infant (see Fig. 423-3).

(see Fig. 423-5) seen in a neonate suggests left ventricular hypertrophy. The exception is a premature infant, who may display a more "mature" ECG than a full-term infant (Fig. 423-7) as a result of lower pulmonary vascular resistance secondary to underdevelopment of the medial muscular layer of the pulmonary arterioles. Some premature infants display a pattern of generalized low voltage across the precordium.

The ECG should always be evaluated systematically to avoid the possibility of overlooking a minor, but important, abnormality. One approach is to begin with an assessment of rate and rhythm, followed by a calculation of the mean frontal-plane QRS axis, measurements of segment intervals, assessment of voltages, and, finally, assessment of ST and T-wave abnormalities.

RATE AND RHYTHM

A brief rhythm strip should be examined to assess whether a P wave always precedes each QRS complex. The P-wave axis should then be estimated as an indication of whether the rhythm is originating from the sinus node. If the atria are situated normally in the chest, the P wave should be upright in leads I and aVF and inverted in lead aVR. With atrial inversion (situs inversus), the P wave may be inverted in lead I. Inverted P waves in leads II and aVF are seen in low atrial, nodal, or junctional rhythms. The absence of P waves indicates a rhythm originating more distally in the conduction system. In this case, the morphologic features of the QRS complexes are important in differentiating a junctional (usually a narrow QRS complex) from a ventricular (usually a wide QRS complex) rhythm.

P WAVES

Tall (>2.5 mm), narrow, and spiked P waves are indicative of **right atrial enlargement** and are seen in congenital pulmonary stenosis,

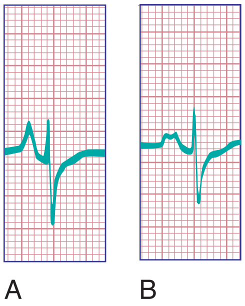

Figure 423-8 **Atrial enlargement. A,** Peaked narrow P waves characteristic of right atrial enlargement. **B,** Wide bifid M-shaped P waves typical of left atrial enlargement.

Ebstein anomaly of the tricuspid valve, tricuspid atresia, and sometimes cor pulmonale. These abnormal waves are most obvious in leads II, V_3R, and V_1 (Fig. 423-8*A*). Similar waves are sometimes seen in thyrotoxicosis. **Broad P waves,** commonly **bifid** and sometimes **biphasic,** are indicative of left atrial enlargement (Fig. 423-8*B*). They are seen in some patients with large left-to-right shunts (ventricular septal defect [VSD], patent ductus arteriosus [PDA]) and with severe mitral stenosis or regurgitation. Flat P waves may be encountered in hyperkalemia.

QRS COMPLEX

Right Ventricular Hypertrophy

For the most accurate assessment of ventricular hypertrophy, pediatric ECGs should include the right precordial lead V_3R or V_4R, or both. The diagnosis of right ventricular hypertrophy depends on demonstration of the following changes (see Fig. 423-6): (1) a qR pattern in the right ventricular surface leads; (2) a positive T wave in leads V_3R-V_4R and V_1-V_3 between the ages of 6 days and 6 yr; (3) a monophasic R wave in V_3R, V_4R, or V_1; (4) an rsR′ pattern in the right precordial leads with the 2nd R wave taller than the initial one; (5) age-corrected increased voltage of the R wave in leads V_3R-V_4R or the S wave in leads V_6-V_7, or both; (6) marked right axis deviation (>120 degrees in patients beyond the newborn period); and (7) complete reversal of the normal adult precordial RS pattern. At least 2 of these changes should be present to support a diagnosis of right ventricular hypertrophy.

Abnormal ventricular loading can be characterized as either systolic (as a result of obstruction of the right ventricular outflow tract, as in pulmonic stenosis) or diastolic (as a result of increased volume load, as in atrial septal defects [ASDs]). These 2 types of abnormal loads result in distinct electrocardiographic patterns. The **systolic overload pattern** is characterized by tall, pure R waves in the right precordial leads. In older children, the T waves in these leads are initially upright and later become inverted. In infants and children <6 yr, the T waves in V_3R-V_4R and V_1 are abnormally upright. The **diastolic overload pattern** (typically seen in patients with ASDs) is characterized by an rsR′ pattern (Fig. 423-9) and a slightly increased QRS duration (minor right ventricular conduction delay). Patients with mild to moderate pulmonary stenosis may also exhibit an rsR′ pattern in the right precordial leads.

Left Ventricular Hypertrophy

The following features indicate the presence of left ventricular hypertrophy (Fig. 423-10): (1) depression of the ST segments and inversion of the T waves in the left precordial leads (V_5, V_6, and V_7), known as a *left ventricular strain* pattern—these findings suggest the presence of a severe lesion; (2) a deep Q wave in the left precordial leads; and (3) increased voltage of the S wave in V_3R and V_1 or the R wave in V_6-V_7, or both. It is important to emphasize that evaluation of left ventricular hypertrophy should not be based on voltage criteria alone. The concepts of systolic and diastolic overload, though not always consistent,

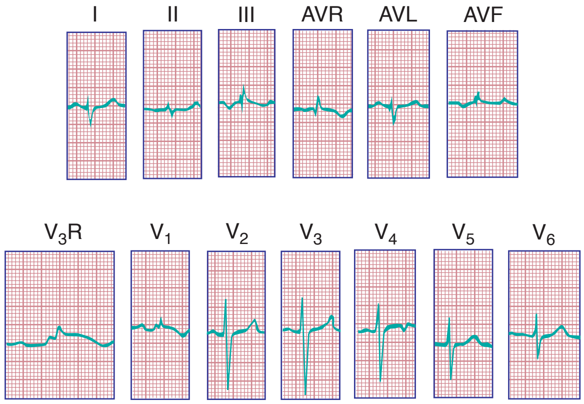

Figure 423-9 Electrocardiogram showing right ventricular conduction delay characterized by an rsR′ pattern in V_1 and a deep S wave in V_6 (V_3R paper speed = 50 mm/sec).

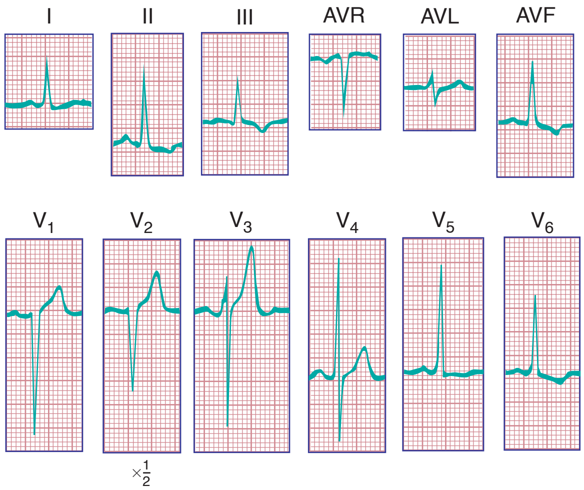

Figure 423-10 **Electrocardiogram showing left ventricular hypertrophy in a 12 yr old child with aortic stenosis.** Note the deep S wave in V_1-V_3 and tall R in V_5. In addition, T-wave inversion is present in leads II, III, aVF, and V_6.

are also useful in evaluating left ventricular enlargement. Severe systolic overload of the left ventricle is suggested by straightening of the ST segments and inverted T waves over the left precordial leads; diastolic overload may result in tall R waves, a large Q wave, and normal T waves over the left precordium. Finally, an infant with an ECG that would be considered "normal" for an older child may, in fact, have left ventricular hypertrophy.

Bundle Branch Block

A complete right bundle-branch block may be congenital or may be acquired after surgery for congenital heart disease, especially when a right ventriculotomy has been performed, as in repair of the tetralogy of Fallot. Congenital left bundle-branch block is rare; this pattern is occasionally seen with cardiomyopathy. A bundle-branch block pattern may be indicative of a bypass tract associated with one of the preexcitation syndromes (see Chapter 435).

P-R AND Q-T INTERVALS

The duration of the P-R interval shortens with increasing heart rate; thus, assessment of this interval should be based on age- and rate-corrected nomograms. A long P-R interval is diagnostic of a **1st-degree heart block,** the cause of which may be congenital, postoperative,

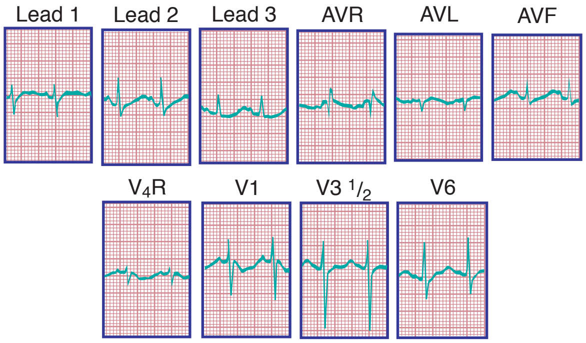

Figure 423-11 Electrocardiogram in hypokalemia (serum potassium, 2.7 mEq/L; serum calcium, 4.8 mEq/L at the time of the tracing). Note the prolongation of electrical systole as evidenced by a widened TU wave, as well as depression of the ST segment in V_4R, V_1, and V_6.

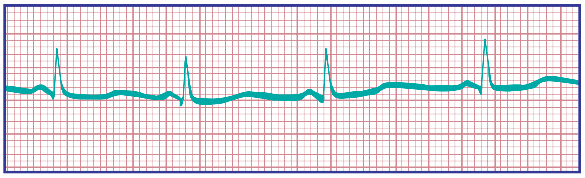

Figure 423-12 Prolonged Q-T interval in a patient with long Q-T syndrome.

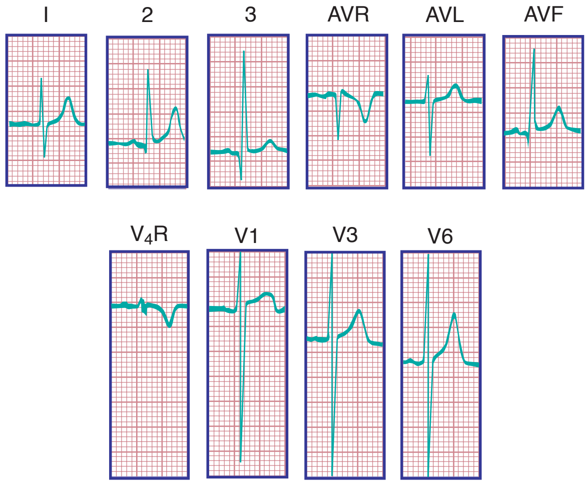

Figure 423-13 Electrocardiogram in hyperkalemia (serum potassium, 6.5 mEq/L; serum calcium, 5.1 mEq/L). Note the tall, tent-shaped T waves, especially in leads I, II, and V_6.

inflammatory (myocarditis, pericarditis, Lyme disease, rheumatic fever), or pharmacologic (digitalis).

The duration of the Q-T interval varies with the cardiac rate; a corrected Q-T interval (Q-Tc) can be calculated by dividing the measured Q-T interval by the square root of the preceding R-R interval. A normal Q-Tc should be <0.45. It is often lengthened with hypokalemia and hypocalcemia; in the former instance, a U wave may be noted at the end of the T wave (Fig. 423-11). There are a number of medications that can also lengthen the Q-T interval. A congenitally prolonged Q-T interval (Fig. 423-12) may also be seen in children with one of the long Q-T syndromes. These patients are at high risk for ventricular arrhythmias, including a form of ventricular tachycardia known as torsades de pointes, and sudden death (see Chapter 435.5).

ST SEGMENT AND T-WAVE ABNORMALITIES

A slight elevation of the ST segment may occur in normal teenagers and is attributed to early repolarization of the heart. In pericarditis, irritation of the epicardium may cause elevation of the ST segment followed by abnormal T-wave inversion as healing progresses. Administration of digitalis is sometimes associated with sagging of the ST segment and abnormal inversion of the T wave.

Depression of the ST segment may also occur in any condition that produces myocardial damage or ischemia, including severe anemia, carbon monoxide poisoning, aberrant origin of the left coronary artery from the pulmonary artery, glycogen storage disease of the heart, myocardial tumors, and mucopolysaccharidoses. An aberrant origin of the left coronary artery from the pulmonary artery may lead to changes indistinguishable from those of acute myocardial infarction in adults. Similar changes may occur in patients with other rare abnormalities of the coronary arteries and in those with cardiomyopathy, even in the presence of normal coronary arteries. These patterns are often misread in young infants because of the unfamiliarity of pediatricians with this "infarct" pattern, and thus a high index of suspicion must be maintained in infants with dilated cardiomyopathy or with symptoms compatible with coronary ischemia (e.g., inconsolable crying).

T-wave inversion may occur in myocarditis and pericarditis, or it may be a sign of either right or left ventricular hypertrophy and strain. Hypothyroidism may produce flat or inverted T waves in association with generalized low voltage. In hyperkalemia, the T waves are commonly of high voltage and are tent-shaped (Fig. 423-13).

423.3 Hematologic Data

Daniel Bernstein

In acyanotic infants with large left-to-right shunts, the onset of heart failure often coincides with the nadir of the normal physiologic anemia of infancy. Increasing the hematocrit in these patients to >40% may decrease shunt volume and result in an improvement in symptoms; however, this form of treatment is generally reserved for infants who are not otherwise surgical candidates (extremely premature infants or those with exceedingly complex congenital heart disease for whom only palliative surgery is possible). In these select infants, regular evaluation of the hematocrit and booster transfusions when appropriate may be helpful in improving growth.

Polycythemia is frequently noted in cyanotic patients with right-to-left shunts. Patients with severe polycythemia are in a delicate balance between the risks of intravascular thrombosis and a bleeding diathesis. The most frequent abnormalities include accelerated fibrinolysis, thrombocytopenia, abnormal clot retraction, hypofibrinogenemia, prolonged prothrombin time, and prolonged partial thromboplastin time. The preparation of cyanotic, polycythemic patients for elective noncardiac surgery, such as dental extraction, includes evaluation and treatment of abnormal coagulation.

Because of the high viscosity of polycythemic blood (hematocrit >65%), patients with cyanotic congenital heart disease are at risk for the development of vascular thromboses, especially of cerebral veins. Dehydration increases the risk of thrombosis, and thus adequate fluid intake must be maintained during hot weather or intercurrent gastrointestinal illnesses. Diuretics should be used with caution in these patients and may need to be decreased if fluid intake is a concern. Polycythemic infants with concomitant **iron deficiency** are at even greater risk for cerebrovascular accidents, probably because of the decreased deformability of microcytic red blood cells. Iron therapy may reduce this risk somewhat, but surgical treatment of the cardiac anomaly is the best therapy.

Severely cyanotic patients should have periodic determinations of hemoglobin and hematocrit. Increasing polycythemia, often associated with headache, fatigue, dyspnea, or a combination of these conditions, is one indication for palliative or corrective surgical intervention. In cyanotic patients with inoperable conditions, partial exchange

transfusion may be required to treat symptomatic individuals whose hematocrit has risen to the 65-70% level. This procedure is not without risk, especially in patients with an extreme elevation in pulmonary vascular resistance. Because these patients do not tolerate wide fluctuations in circulating blood volume, blood should be replaced with fresh-frozen plasma or albumin.

423.4 Echocardiography

Daniel Bernstein

Transthoracic echocardiography has replaced invasive studies such as cardiac catheterization for the *initial diagnosis* of most forms of congenital heart disease. The echocardiographic examination can be used to evaluate cardiac structure in congenital heart lesions, estimate intracardiac pressures and gradients across stenotic valves and vessels, quantitate cardiac contractile function (both systolic and diastolic), determine the direction of flow across a defect, examine the integrity of the coronary arteries, and detect the presence of vegetations from endocarditis, as well as the presence of pericardial fluid, cardiac tumors, and chamber thrombi. Echocardiography may also be used to assist in the performance of interventional procedures, including pericardiocentesis, balloon atrial septostomy (see Chapter 431.2), atrial or VSD closure and endocardial biopsy, and in the placement of flow-directed pulmonary artery (Swan-Ganz) monitoring catheters. **Transesophageal echocardiography** is used routinely to monitor ventricular function in patients during surgical procedures and can provide an immediate assessment of the results of surgical repair of congenital heart lesions. A complete transthoracic echocardiographic examination usually entails a combination of M-mode and 2-dimensional (2D) imaging, as well as pulsed, continuous, and color Doppler flow studies. Doppler tissue imaging provides a more quantitative assessments of ventricular function. Three-dimensional (3D) echocardiography provides valuable information regarding cardiac morphology.

M-MODE ECHOCARDIOGRAPHY

M-mode echocardiography displays a 1-dimensional slice of cardiac structure varying over time (Fig. 423-14). It is used mostly for the measurement of cardiac dimensions (wall thickness and chamber size) and cardiac function (fractional shortening, wall thickening). M-mode echocardiography is also useful for assessing the motion of intracardiac structures (opening and closing of valves, movement of free walls and septa) and the anatomy of valves (Fig. 423-15). The most frequently used index of cardiac function in children is percent fractional shortening (%FS), which is calculated as (LVED − LVES)/LVED, where LVED is left ventricular (LV) dimension at end-diastole and LVES is

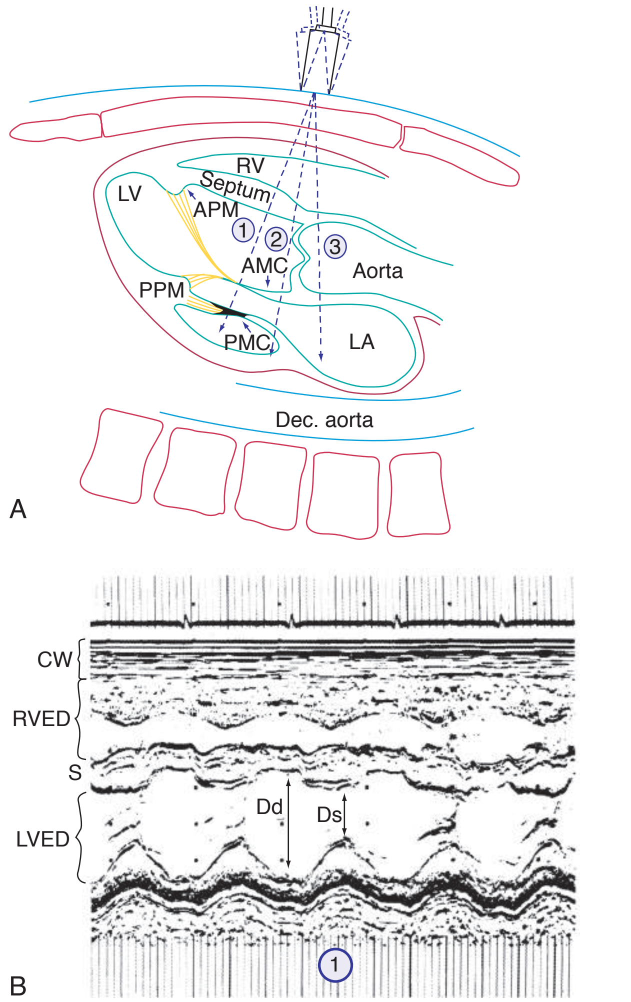

Figure 423-14 M-mode echocardiogram. **A,** Diagram of a sagittal section of a heart showing the structures traversed by the echo beam as it is moved superiorly to positions *(1), (2),* and *(3).* AMC, anterior mitral cusp; APM, anterior papillary muscle; Dec. aorta, descending aorta; LA, left atrium; LV, left ventricle; PMC, posterior mitral cusp; PPM, posterior papillary muscle; RV, right ventricle. **B,** Echocardiogram from transducer position *(1);* this view is the best one for measuring cardiac dimensions and fractional shortening. Fractional shortening is calculated as (LVED − LVES)/LVED. CW, chest wall; Ds, LV dimension in systole; LVED, LV dimension at end-diastole (Dd); RVED, RV dimension at end-diastole.

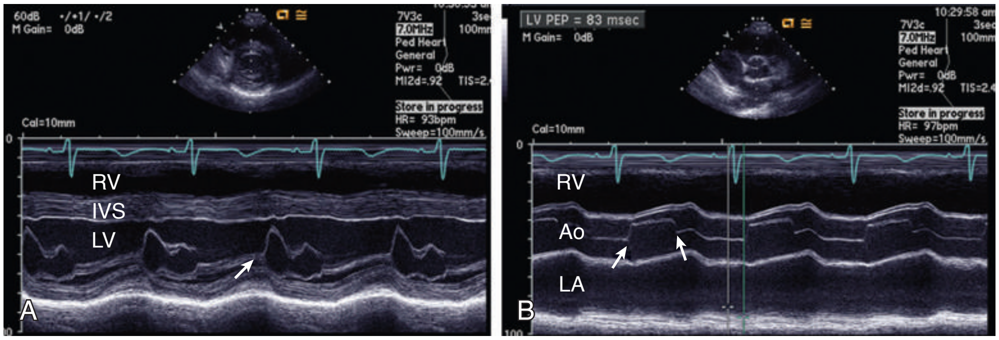

Figure 423-15 M-mode echocardiograms. The small figure at the top of each panel shows the 2D parasternal short axis echo image from which the M-modes are derived. The cursor can be seen midway through the image, indicating the one-dimensional line through which the M-mode is being sampled. **A,** M-mode echocardiogram of a normal mitral valve. *Arrow* shows the opening of the anterior leaflet in early diastole (see ECG tracing above for reference). **B,** M-mode echocardiogram of a normal aortic valve. The opening and closing of the aortic leaflets in systole are outlined by the 2 *arrows.* Ao, aorta; IVS, interventricular septum; LV, left ventricle; RV, right ventricle.

LV dimension at end-systole. Normal fractional shortening is approximately 28-40%. Other M-mode indices of cardiac function include the mean velocity of fiber shortening (mean V_{CF}), systolic time intervals (LVPEP = LV preejection period, LVET = LV ejection time), and isovolemic contraction time. More sophisticated indices of cardiac function can be derived noninvasively with the assistance of echocardiography (pressure–volume relationship, end-systolic wall stress–strain relationship).

TWO-DIMENSIONAL ECHOCARDIOGRAPHY

Two-dimensional echocardiography provides a real-time image of cardiac structures. With 2D echocardiography, the contracting heart is imaged in real time using several standard views, including parasternal long axis (Fig. 423-16), parasternal short axis (Fig. 423-17), apical four chamber (Fig. 423-18), subcostal (Fig. 423-19), and suprasternal (Fig. 423-20) windows, each of which emphasizes specific structures. Two-dimensional echocardiography has replaced cardiac angiography for the preoperative diagnosis of most, but not all congenital heart lesions. When information from the cardiac examination or other studies is not consistent with the echocardiogram (e.g., the size of a left-to-right shunt), cardiac catheterization remains an important tool to confirm the anatomic diagnosis and evaluate the degree of physiologic derangement.

DOPPLER ECHOCARDIOGRAPHY

Doppler echocardiography displays blood flow in cardiac chambers and vascular channels based on the change in frequency imparted to

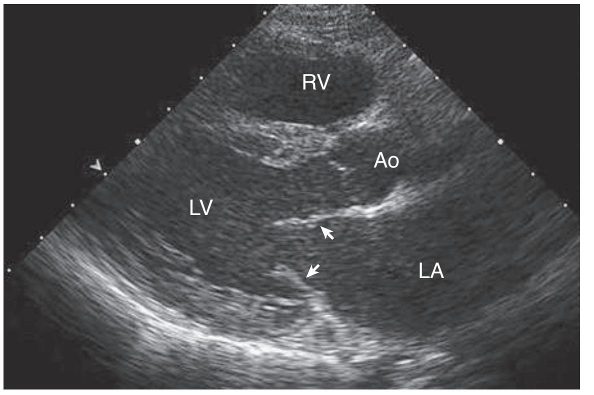

Figure 423-16 Normal parasternal long axis echocardiographic window. The transducer is angulated slightly posteriorly, imaging the left-sided cardiac structures. If the transducer were to be angulated more anteriorly, the right ventricular structures would be imaged. The mitral valve leaflets can be seen in partially open position in early diastole *(arrowheads).* The closed aortic valve leaflets can be seen just below the label Ao. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

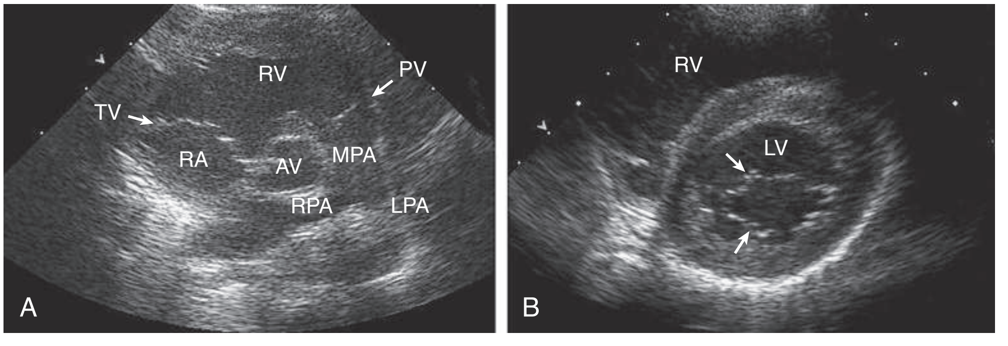

Figure 423-17 Normal parasternal short axis echocardiographic windows. A, With the transducer angled superiorly and rightwards, the aortic valve (AV) is imaged, surrounded by both inflow and outflow portions of the right ventricle (RV). LPA, left pulmonary artery; MPA, main pulmonary artery; PV, pulmonary valve; RA, right atrium; RPA, right pulmonary artery; TV, tricuspid valve. **B,** With the transducer angled inferiorly and leftward, the left ventricular chamber is imaged along with cross-sectional view of the mitral valve *(arrows).* LV, left ventricle; RV, right ventricle.

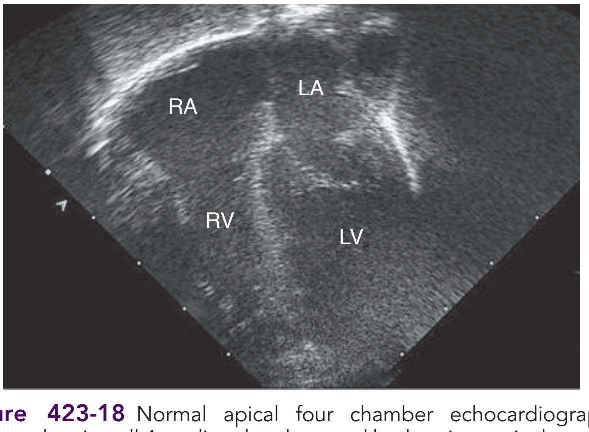

Figure 423-18 Normal apical four chamber echocardiographic window showing all 4 cardiac chambers and both atrioventricular valves opened in diastole. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

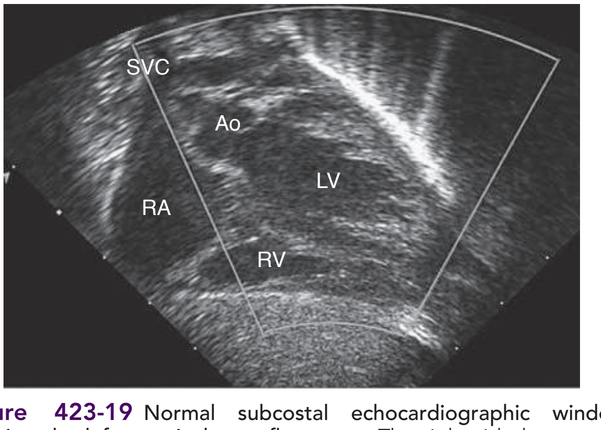

Figure 423-19 Normal subcostal echocardiographic window showing the left ventricular outflow tract. The right-sided structures are not fully imaged in this view. Ao, ascending aorta; LV, left ventricle; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

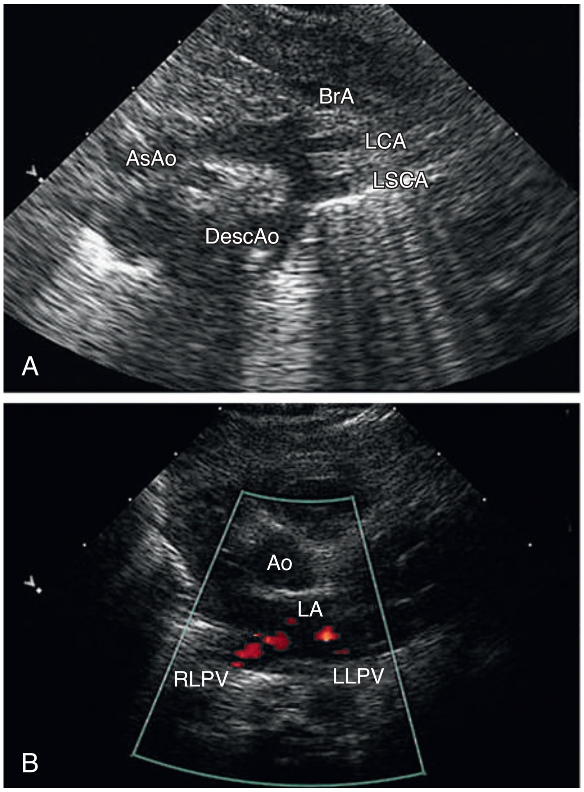

Figure 423-20 **A,** Normal suprasternal echocardiographic window showing the aortic arch and its major branches. AsAo, ascending aorta; BrA, brachiocephalic artery; DescAo, descending aorta; LCA, left carotid artery; LSCA, left subclavian artery. **B,** Normal high parasternal window showing color Doppler imaging of normal pulmonary venous return to the left atrium (LA) of both right (RLPV) and left (LLPV) lower pulmonary veins.

a sound wave by the movement of erythrocytes. In pulsed Doppler and continuous wave Doppler, the speed and direction of blood flow in the line of the echo beam change the transducer's reference frequency. This frequency change can be translated into volumetric flow (L/min) data for estimating systemic or pulmonary blood flow and into pressure (mm Hg) data for estimating gradients across the semilunar or atrioventricular valves or across septal defects or vascular communications such as shunts. Color Doppler permits highly accurate assessment of the presence and direction of intracardiac shunts and allows identification of small or multiple left-to-right or right-to-left shunts (Fig. 423-21). The severity of valvular insufficiency can be evaluated with both pulsed and color Doppler (Fig. 423-22). Alterations in venous Doppler flow patterns can be used to detect abnormalities of systemic and pulmonary veins and alterations of atrioventricular valve Doppler flow patterns can be used to assess ventricular diastolic functional abnormalities.

M-mode, 2D, and Doppler echocardiographic methods of assessing LV systolic and diastolic function (e.g., end-systolic wall stress, dobutamine stress echocardiography, and Doppler tissue imaging) have proved useful in the serial assessment of patients at risk for the development of both systolic and diastolic ventricular dysfunction and ventricular dyssynchrony (where the coordination of left and right ventricular contraction is abnormal). Such patients include those with cardiomyopathies, those receiving anthracycline drugs for cancer chemotherapy, those at risk for iron overload, and those being monitored for rejection or coronary artery disease after heart transplantation.

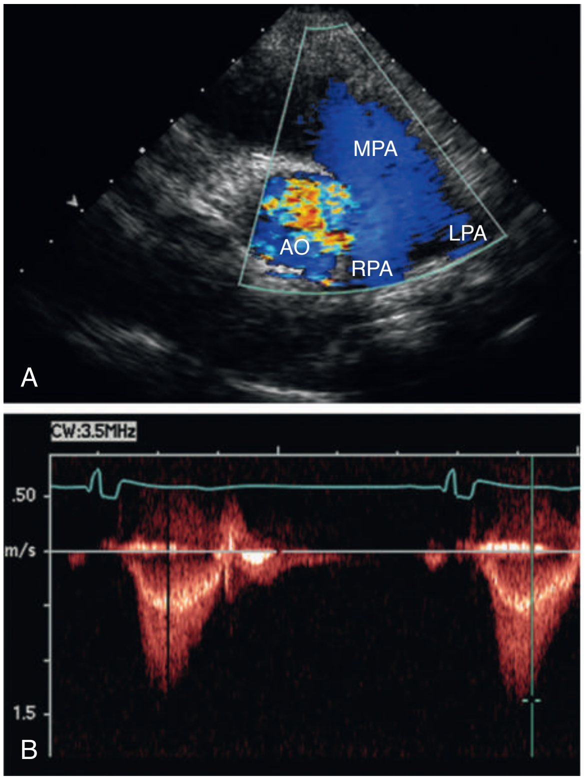

Figure 423-21 **Color and pulsed Doppler evaluation of pulmonary arterial flow. A,** Color Doppler evaluation of a parasternal short axis view showing normal flow through the pulmonary valve to the main and branch pulmonary arteries. The color of the Doppler flow is blue, indicating that the flow is moving away from the transducer (which is located at the top of the figure, at the apex of the triangular ultrasound window). Note that the color assigned to the Doppler signal does not indicate the oxygen saturation of the blood. AO, aorta; LPA, left pulmonary artery; MPA, main pulmonary artery; RPA, right pulmonary artery. **B,** Pulsed wave Doppler flow pattern through the pulmonary valve showing a low velocity of flow (<1.5 m/sec), indicating the absence of a pressure gradient across the valve. The envelope of the flow signal is below the line, indicating that the flow is moving away from the transducer.

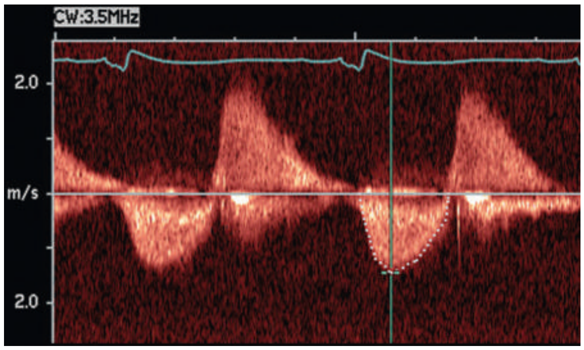

Figure 423-22 Doppler evaluation of a patient who had previously undergone repair of tetralogy of Fallot and who has mild pulmonary stenosis and moderate pulmonary regurgitation. The tracing shows the to-and-fro flow across the pulmonary valve with the signal below the line representing forward flow in systole (see ECG tracing for reference) and the signal above the line representing regurgitation during diastole.

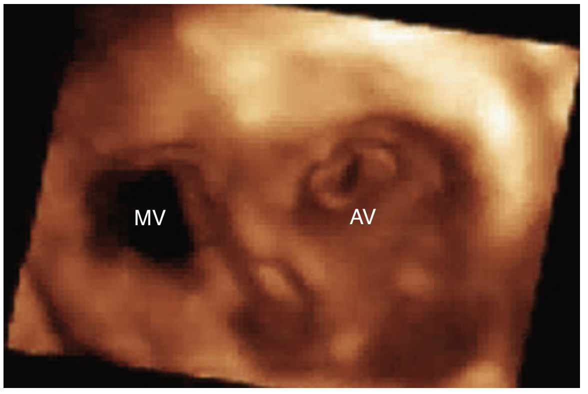

Figure 423-23 **Three-dimensional echocardiogram showing a short axis view of the left ventricle.** AV, aortic valve; MV, mitral valve. *(Courtesy of Dr. Norman Silverman, Stanford University, Stanford, CA.)*

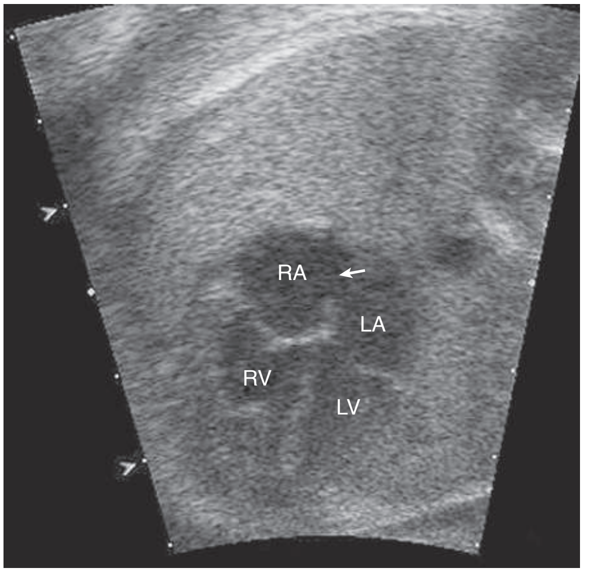

Figure 423-24 **Normal 4-chamber view echocardiogram on a fetus at 20 wk of gestation.** The foramen ovale *(arrow)* can be seen between the right and left atria. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

THREE-DIMENSIONAL ECHOCARDIOGRAPHY

Real-time 3D echocardiographic reconstruction is valuable for the assessment of cardiac morphology (Fig. 423-23). Details of valve structure, the size and location of septal defects, abnormalities of the ventricular myocardium, and details of the great vessels, which may not be as readily apparent using 2D imaging, can often be appreciated on 3D echocardiography. Reconstruction of the view that the surgeon will encounter in the operating room makes this technique a valuable adjunct for preoperative imaging.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography is an extremely sensitive imaging technique that produces a clearer view of smaller lesions such as vegetations in endocarditis, especially in larger patients. It is useful in visualizing posteriorly located structures such as the atria, aortic root, and atrioventricular valves. Transesophageal echocardiography is extremely useful as an intraoperative technique for monitoring cardiac function during both cardiac and noncardiac surgery and for screening for residual cardiac defects after the patient in initially weaned from cardiopulmonary bypass but before they are disconnected from the bypass circuit. This technique has been especially helpful in evaluating the degree of residual regurgitation or stenosis after valve repairs and in searching for small muscular VSDs that may have been missed during the closure of larger defects.

FETAL ECHOCARDIOGRAPHY

Fetal echocardiography can be used to evaluate cardiac structures or disturbances in cardiac rhythm (Fig. 423-24). Perinatologists often detect gross abnormalities in cardiac structure on routine obstetric ultrasonography or may refer the patient because of unexplained hydrops fetalis, a family history of congenital heart disease, or a maternal condition associated with fetal cardiac pathology such as gestational diabetes. Fetal echocardiography is capable of diagnosing most significant congenital heart lesions as early as 17-19 wk of gestation; accuracy at this early stage is limited and families should understand that these studies cannot totally eliminate the possibility of congenital heart disease. Serial fetal echocardiograms have also demonstrated the importance of flow disturbance in the pathogenesis of congenital heart disease; such studies can show the intrauterine progression of a moderate lesion, such as aortic stenosis, into a more severe lesion, such as hypoplastic left heart syndrome. M-mode echocardiography can diagnose rhythm disturbances in the fetus and can determine the success of antiarrhythmic therapy administered to the mother. A screening fetal echocardiogram is recommended for women with a previous child or 1st-degree relative with congenital heart disease, for those who are at higher risk of having a child with cardiac disease (insulin-dependent diabetics, patients with exposure to teratogenic drugs during early pregnancy), and in any fetus in which a chromosomal abnormality is suspected or confirmed.

Early detection provides the opportunity to counsel and educate the parents about the severity of the cardiac lesion and potential therapeutic or palliative care options. Referral to a high-risk perinatal service is then performed, for further ultrasound screening for associated anomalies of other organs and potential amniocentesis for karyotyping. For those fetuses with ductal dependent lesions, delivery can be planned at a tertiary care center, avoiding the requirement for postnatal transport of an unstable infant. For those fetuses with complex congenital heart disease at high risk for complications immediately at birth (e.g., hypoplastic left heart syndrome with intact atrial septum), delivery can be arranged with an operating room and surgeon standing by.

Bibliography is available at Expert Consult.

423.5 Exercise Testing

Daniel Bernstein

The normal cardiorespiratory system adapts to the extensive demands of exercise with a several-fold increase in oxygen consumption and cardiac output. Because of the large reserve capacity for exercise, significant abnormalities in cardiovascular performance may be present without symptoms at rest or during ordinary activities. When patients are evaluated in a resting state, significant abnormalities in cardiac function may not be appreciated, or if detected, their implications for quality of life may not be recognized. Permission for children with cardiovascular disease to participate in various forms of physical activity is frequently based on totally subjective criteria. As the importance of aerobic exercise is increasingly recognized, even for children with complex congenital heart lesions, exercise testing can provide a quantitative evaluation of the child's ability to safely participate in both competitive and noncompetitive sports. Exercise testing can also play an important role in evaluating symptoms and quantitating the severity of cardiac abnormalities.

In older children, exercise studies are generally performed on a graded treadmill apparatus with timed intervals of increasing grade

and speed. In younger children, exercise studies are often performed on a bicycle ergometer. Many laboratories have the capacity to measure both cardiac and pulmonary function noninvasively during exercise. This allows measurement of both resting and maximal oxygen consumption (Vo_{2max}) and the point at which anaerobic threshold is reached, important indicators of cardiovascular fitness.

As a child grows, the capacity for work is enhanced with increased body size and skeletal muscle mass. All indices of cardiopulmonary function do not increase in a uniform manner. A major response to exercise is an increase in cardiac output, principally achieved through an increase in heart rate, but stroke volume, systemic venous return, and pulse pressure are also increased. Systemic vascular resistance is greatly decreased as the blood vessels in working muscle dilate in response to increasing metabolic demands. As the child becomes older and larger, the response of the heart rate to exercise remains prominent, but cardiac output increases because of growing cardiac volume capacity and, hence, stroke volume. Responses to dynamic exercise are not dependent solely on age. For any given body surface area, boys have a larger stroke volume than size-matched girls. This increase is also mediated by posture. Augmentation of stroke volume with upright, dynamic exercise is facilitated by the pumping action of working muscles, which overcomes the static effect of gravity and increases systemic venous return.

Dynamic exercise testing defines not only endurance and exercise capacity but also the effect of such exercise on myocardial blood flow and cardiac rhythm. Significant ST segment depression reflects abnormalities in myocardial perfusion, for example, the subendocardial ischemia that commonly occurs during exercise in children with hypertrophied left ventricles. The **exercise ECG** is considered abnormal if the ST segment depression is >2 mm and extends for at least 0.06 sec after the J point (onset of the ST segment) in conjunction with a horizontal-, upward-, or downward-sloping ST segment. Provocation of rhythm disturbances during an exercise study is an important method of evaluating selected patients with known or suspected rhythm disorders. The effect of pharmacologic management can also be tested in this manner.

423.6 MRI, MRA, CT, and Radionuclide Studies

Daniel Bernstein

Magnetic resonance imaging (MRI) and **magnetic resonance angiography (MRA)** are extremely helpful in the diagnosis and management of patients with congenital heart disease. These techniques produce tomographic images of the heart in any projection (Fig. 423-25), with excellent contrast resolution of fat, myocardium, and lung, as well as moving blood from blood vessel walls. MRI is useful in evaluating areas that are less well visualized by echocardiography, such as distal branch pulmonary artery anatomy and anomalies in systemic and pulmonary venous return.

MRA allows the acquisition of images in several tomographic planes. Within each plane, images are obtained at different phases of the cardiac cycle. Thus, when displayed in a dynamic "cine" format, changes in wall thickening, chamber volume, and valve function can be displayed and analyzed. Blood flow velocity and blood flow volume can be calculated. MRA is an excellent technique for following patients serially after repair of complex congenital heart disease, such as tetralogy of Fallot. In these patients, MRA can be used to assess right ventricular volume and mass as well as quantify the amount of regurgitation through either the pulmonary or tricuspid valve. Other MRI techniques, such as myocardial delayed enhancement, can be used to quantify areas of myocardial scar in patients with cardiomyopathy or in patients after congenital heart disease repair, especially tetralogy of Fallot. **Magnetic resonance spectroscopy,** predominantly a research tool at present, provides a means of demonstrating relative concentrations of high-energy metabolites (adenosine triphosphate, adenosine diphosphate, inorganic phosphate, and phosphocreatine) within regions of the working myocardium.

Computer processing of MRA images allows the noninvasive visualization of the cardiovascular system from inside of the heart or vessels, a technique known as *fly-through imaging.* These images allow the cardiologist to image the interiors of various cardiovascular structures (Fig. 423-26). These imaging techniques are especially helpful in imaging complex peripheral arterial stenoses, especially after balloon angioplasty.

CT scanning can now be used to perform rapid, respiration-gated cardiac imaging in children with resolutions down to 0.5 mm. Three-dimensional reconstruction of CT images (Fig. 423-27) are especially useful in evaluating branch pulmonary arteries, anomalies in systemic and pulmonary venous return, and great vessel anomalies such as coarctation of the aorta.

Radionuclide angiography may be used to detect and quantify shunts and to analyze the distribution of blood flow to each lung. This technique is particularly useful in quantifying the volume of blood flow distribution between the 2 lungs in patients with abnormalities of the pulmonary vascular tree or after a shunt operation (Blalock-Taussig or Glenn), or to quantify the success of balloon angioplasty and intravascular stenting procedures. Gated blood pool scanning can be used to calculate hemodynamic measurements, quantify valvular regurgitation, and detect regional wall motion abnormalities. Thallium imaging can be performed to evaluate cardiac muscle perfusion. These methods can be used at the bedside of seriously ill children and can be performed serially, with minimal discomfort and low radiation exposure.

423.7 Diagnostic and Interventional Cardiac Catheterization

Daniel Bernstein

The catheterization laboratory has become the site of high-technology interventional procedures, allowing for the nonsurgical repair or palliation of heart defects that once required open heart surgery. Some centers have developed hybrid catheterization laboratories, combining standard fluoroscopic imaging with an operating suite, allowing combined approaches to treat complex congenital heart lesions.

DIAGNOSTIC CARDIAC CATHETERIZATION

Diagnostic catheterization is still performed: (1) to assist in the initial diagnosis of some complex congenital heart lesions (e.g., tetralogy of Fallot with pulmonary atresia and major aortopulmonary collateral arteries, pulmonary atresia with intact ventricular septum and coronary sinusoids, hypoplastic left-heart syndrome with mitral stenosis); (2) in cases in which other imaging studies are equivocal; (3) in patients for whom hemodynamic assessment is critical (to determine the size of a left-to-right shunt in borderline cases, or to determine the presence or absence of pulmonary vascular disease in an older patient with a left-to-right shunt); (4) between stages of repair of complex congenital heart disease (e.g., hypoplastic left- or right-heart syndromes); (5) for myocardial biopsy in the diagnosis of cardiomyopathy or in

screening for cardiac rejection after cardiac transplantation; and (6) for electrophysiologic study in the evaluation of cardiac arrhythmias (see Chapter 435).

Cardiac catheterization should be performed with the patient in as close to a basal state as possible. Conscious sedation is routine; if a deeper level of general anesthesia is required, careful choice of an anesthetic agent is warranted to avoid depression of cardiovascular function and subsequent distortion of the calculations of cardiac output, pulmonary and systemic vascular resistance, and shunt ratios.

Cardiac catheterization in critically ill infants with congenital heart disease should be performed in a center where a pediatric cardiovascular surgical team is available in the event that an operation is required immediately afterward. The complication rate of cardiac catheterization and angiography is greatest in critically ill infants; they must be studied in a thermally neutral environment and treated quickly for hypothermia, hypoglycemia, acidosis, or excessive blood loss.

Catheterization may be limited to the right-sided cardiac structures, the left-sided structures, or both the right and left sides of the heart. The catheter is passed into the heart under fluoroscopic guidance through a percutaneous entry point in a femoral or jugular vein. In infants and in a number of older children, the left side of the heart can be accessed by passing the catheter across a patent foramen ovale to the left atrium and left ventricle. If the foramen is closed, the left side of the heart can be catheterized by passing the catheter retrograde via a percutaneous entry site in the femoral artery, or if necessary, via a transatrial septal puncture. The catheter can be manipulated through abnormal intracardiac defects (ASDs, VSDs). Blood samples are obtained for measuring oxygen saturation and calculating shunt volumes, pressures are measured for calculating gradients and valve areas, and radiopaque contrast is injected to delineate cardiac and vascular structures. A catheter with a thermosensor tip can be used to measure cardiac output by thermodilution. Specialized catheters can be used to measure more sophisticated indices of cardiac function: Those with pressure-transducer tips can be utilized to measure the first derivative of LV pressure (dP/dt); and conductance catheters can be used to generate pressure-volume loops, from which indices of both contractility (end-systolic elastance) and relaxation can be derived. Complete hemodynamics can be calculated, including cardiac output, intracardiac left-to-right and right-to-left shunts, and systemic and pulmonary vascular resistances. Figure 423-28 depicts normal circulatory dynamics.

THERMODILUTION MEASUREMENT OF CARDIAC OUTPUT

The thermodilution method for measuring cardiac output is performed with a flow-directed, thermistor-tipped, pulmonary artery (Swan-Ganz) catheter. A known change in the heat content of the blood is induced at one point in the circulation (usually the right atrium or inferior vena cava) by injecting room temperature saline, and the resultant change in temperature is detected at a point downstream (usually the pulmonary artery). This method is used to measure cardiac output in the catheterization laboratory in patients without shunts. Monitoring cardiac output by the thermodilution method can occasionally be useful in managing critically ill infants and children in an intensive care setting after cardiac surgery or in the presence of shock. In this case, a triple-lumen catheter is used for both cardiac output determination and measurement of pulmonary artery and pulmonary capillary wedge pressure.

ANGIOCARDIOGRAPHY

The major blood vessels and individual cardiac chambers may be visualized by selective angiocardiography, the injection of contrast material into specific chambers or great vessels. This method allows identification of structural abnormalities without interference from the superimposed shadows of normal chambers. Fluoroscopy is used to visualize the catheter as it passes through the various heart chambers. After the cardiac catheter is properly placed in the chamber to be studied, a small amount of contrast medium is injected with a power injector, and cineangiograms are exposed at rates ranging from 15-60 frames/sec.

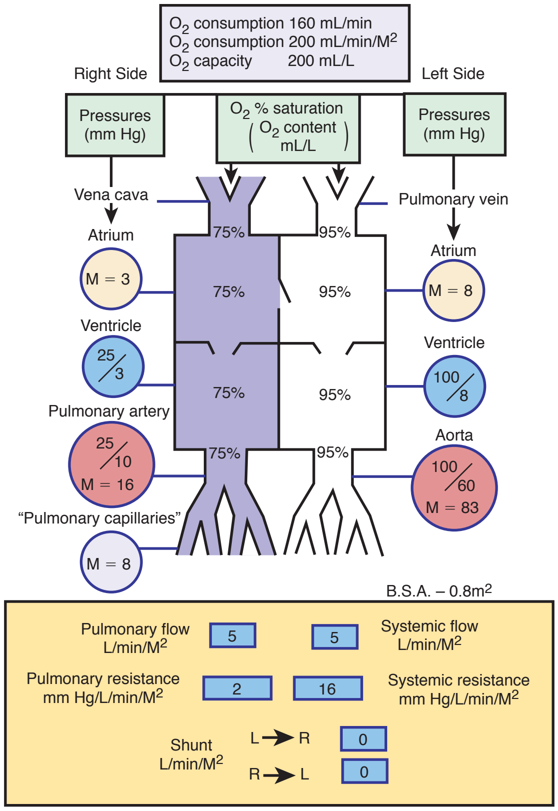

Figure 423-28 Diagram of normal circulatory dynamics with pressure readings, oxygen content, and percent saturation. B.S.A., body surface area. *(Modified from Nadas AS, Fyler DC:* Pediatric cardiology, *ed 3, Philadelphia, 1972, WB Saunders.)*

Modern catheterization labs utilize digital imaging technology, allowing for a significant reduction in radiation exposure. Biplane cineangiocardiography allows detailed evaluation of specific cardiac chambers and blood vessels in 2 planes simultaneously with the injection of a single bolus of contrast material. This technique is standard in pediatric cardiac catheterization laboratories and allows one to minimize the volume of contrast material used, which is safer for the patient. Various angled views (e.g., left anterior oblique, cranial angulation) are used to display specific anatomic features best in individual lesions.

Rapid injection of contrast medium under pressure into the circulation is not without risk, and each injection should be carefully planned. Contrast agents consist of hypertonic solutions, with some containing organic iodides, which can cause complications, including nausea, a generalized burning sensation, central nervous system symptoms, renal insufficiency, and allergic reactions. Intramyocardial injection is generally avoided by careful placement of the catheter before injection. Hypertonicity of the contrast medium may result in transient myocardial depression and a drop in blood pressure, followed soon afterward by tachycardia, an increase in cardiac output, and a shift of interstitial fluid into the circulation. This shift can transiently increase the symptoms of heart failure in critically ill patients.

INTERVENTIONAL CARDIAC CATHETERIZATION

Catheter treatment is the standard of practice for most cases of isolated pulmonary or aortic valve stenosis (see Fig. 421-4) as well as for re-coarctation of the aorta. A special catheter with a sausage-shaped balloon at the distal end is passed through the obstructed valve. Rapid filling of the balloon with a mixture of contrast material and saline solution results in tearing of the stenotic valve tissue, usually at the site of inappropriately fused raphe. Valvular pulmonary stenosis can be treated successfully by balloon angioplasty; in most patients, angioplasty has replaced surgical repair as the initial procedure of choice.

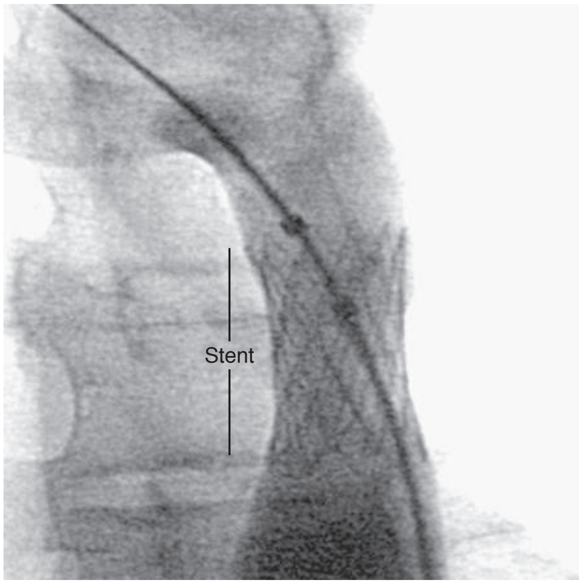

Figure 423-29 Intravascular stent placed in the descending aorta for treatment of recurrent coarctation of the aorta.

The clinical results of this procedure are similar to those obtained by open heart surgery, but without the need for sternotomy or prolonged hospitalization. Balloon valvuloplasty for aortic stenosis has also yielded excellent results, although, as with surgery, aortic stenosis often recurs as the child grows and multiple procedures may thus be required. One complication of both valvuloplasty and surgery is the creation of valvular insufficiency. This complication has more serious implications when it occurs on the aortic vs the pulmonary side of the circulation because regurgitation is less-well tolerated at systemic arterial pressures. Balloon angioplasty is the procedure of choice for patients with restenosis of coarctation of the aorta after earlier surgery. It is controversial whether angioplasty is the best procedure for native (unoperated) coarctation of the aorta because of reports of later aneurysm formation and most centers still refer primary coarctation in infants and young children for surgical repair. However, in older patients with previously undiagnosed coarctation, especially those with decreased LV function, primary angioplasty with possible stent placement may be considered. Other applications of the balloon angioplasty technique include amelioration of mitral stenosis, dilation of surgical conduits (Mustard or Senning atrial baffles), relief of branch pulmonary artery narrowing, dilation of systemic or pulmonary venous obstructions, and the long-used balloon atrial septostomy (Rashkind procedure) for transposition of the great arteries (see Chapter 431.2).

Interventional catheterization techniques are being adapted for use in the **fetus** with lesions such as aortic stenosis in an attempt to prevent their progression to more complex lesions such as hypoplastic left heart syndrome. In these procedures, after administration of appropriate anesthesia, a needle is passed through the maternal abdominal wall, the uterine wall, and the fetal chest wall and directly into the fetal left ventricle (see Fig. 425-13). A coronary angioplasty balloon catheter is passed through the needle and across the stenotic aortic valve, which is then dilated. With the restoration of normal LV blood flow, it is to be hoped that normal LV growth potential is restored. Midterm results with this technique in a growing number of patients show mixed results with good ventricular growth leading to a 2-ventricle circulation in approximately 25% of patients.

In patients with branch pulmonary artery stenoses, the previously mixed results with balloon angioplasty alone have been enhanced with the use of **intravascular stents** (Fig. 423-29) delivered over a balloon catheter and expanded within the vessel lumen. Once placed, they can often be dilated to successively greater sizes as the patient grows, although their use in younger infants and children is limited by the extent to which they can be further expanded. Research into biodissolvable stents may solve this problem in the future. Stents are also being used in adolescents and young adults with coarctation of the aorta.

Closure of a small PDA is routinely achieved with catheter-delivered coils (see Fig. 420-11), whereas a larger PDA can be closed with a variety of sandwich-type devices. Closure of anomalous vascular connections (coronary fistulas, venovenous collaterals in cyanotic heart lesions) can also be achieved using coils. Secundum ASDs are now routinely closed with a double-disc occluder device (see Fig. 420-3). Versions of these devices are currently in clinical trials for closure of surgically hard-to-reach muscular VSDs and even for the more common perimembranous VSD. Catheter-delivered devices may also be used as an adjunct to complex surgical repairs (dilation or stenting of branch pulmonary artery or pulmonary vein stenosis or closure of a difficult to reach muscular VSD). High-risk patients undergoing the Fontan operation (see Chapter 430.4) often have a small fenestration created between the right and left sides of the circulation to serve as a "popoff valve" for high right-sided pressure in the early surgical period. Patients with these "fenestrated Fontans" are usually candidates for subsequent closure of the fenestration with a catheter-delivered device.

Section 3

Congenital Heart Disease

Chapter 424

Epidemiology and Genetic Basis of Congenital Heart Disease

Daniel Bernstein

PREVALENCE

Congenital heart disease occurs in approximately 0.8% of live births. The incidence is higher in stillborns (3-4%), spontaneous abortuses (10-25%), and premature infants (approximately 2% excluding patent ductus arteriosus [PDA]). This overall incidence does not include mitral valve prolapse, PDA of preterm infants, and bicuspid aortic valves (present in 1-2% of adults). Congenital cardiac defects have a wide spectrum of severity in infants: approximately 2-3 in 1,000 newborn infants will be symptomatic with heart disease in the 1st yr of life. The diagnosis is established by 1 wk of age in 40-50% of patients with congenital heart disease and by 1 mo of age in 50-60% of patients. With advances in both palliative and corrective surgery, the number of children with congenital heart disease surviving to adulthood has increased dramatically. Despite these advances, congenital heart disease remains the leading cause of death in children with congenital malformations. Table 424-1 summarizes the relative frequency of the most common congenital cardiac lesions.

Most congenital defects are well tolerated in the fetus because of the parallel nature of the fetal circulation. Even the most severe cardiac defects (e.g., hypoplastic left-heart syndrome) can usually be well compensated for by the fetal circulation. In this example, the entire fetal

Table 424-1 Relative Frequency of Major Congenital Heart Lesions*

LESION	% OF ALL LESIONS
Ventricular septal defect	35-30
Atrial septal defect (secundum)	6-8
Patent ductus arteriosus	6-8
Coarctation of aorta	5-7
Tetralogy of Fallot	5-7
Pulmonary valve stenosis	5-7
Aortic valve stenosis	4-7
D-Transposition of great arteries	3-5
Hypoplastic left ventricle	1-3
Hypoplastic right ventricle	1-3
Truncus arteriosus	1-2
Total anomalous pulmonary venous return	1-2
Tricuspid atresia	1-2
Single ventricle	1-2
Double-outlet right ventricle	1-2
Others	5-10

*Excluding patent ductus arteriosus in preterm neonates, bicuspid aortic valve, physiologic peripheral pulmonic stenosis, and mitral valve prolapse.

cardiac output would be ejected by the right ventricle via the ductus arteriosus into both the descending and ascending aortae (the latter filling in a retrograde fashion), so that fetal organ blood flow would be minimally perturbed. Because the placenta provides for gas exchange and the normal fetal circulation has mixing between more highly and more poorly oxygenated blood, fetal organ oxygen delivery is also not dramatically affected. It is only after birth when the fetal pathways (ductus arteriosus and foramen ovale) begin to close that the full hemodynamic impact of an anatomic abnormality becomes apparent. One notable exception is the case of severe regurgitant lesions, most commonly of the tricuspid valve. In these lesions (e.g., Ebstein anomaly or severe right ventricular outflow obstruction [see Chapter 430.7]), the parallel fetal circulation cannot compensate for the volume load imposed on the right side of the heart. In utero heart failure, often with fetal pleural and pericardial effusions, and generalized ascites (nonimmune hydrops fetalis) may occur.

Although the most significant transitions in circulation occur in the immediate perinatal period, the circulation continues to undergo changes after birth, and these later changes may also have a hemodynamic impact on cardiac lesions and their apparent incidence. As pulmonary vascular resistance falls in the 1st several weeks of life, left-to-right shunting through intracardiac defects increases and symptoms become more apparent. Thus, in patients with a ventricular septal defect (VSD), heart failure is often first noticed between 1 and 3 mo of age (see Chapter 426.6). The severity of various defects can also change dramatically with growth; some VSDs may become smaller and even close as the child ages. Alternatively, stenosis of the aortic or pulmonary valve, which may be only moderate in the newborn period, may become worse if valve orifice growth does not keep pace with patient growth (see Chapter 427.5). The physician should always be alert for associated congenital malformations, which can adversely affect the patient's prognosis (see Table 422-2 in Chapter 422).

ETIOLOGY

The cause of most congenital heart defects is still unknown. Many cases of congenital heart disease are multifactorial and result from a combination of genetic predisposition and an as-yet-to-be-determined environmental stimulus. A small percentage of congenital heart lesions are related to known chromosomal abnormalities, in particular, trisomy 21, 13, and 18 and Turner syndrome; heart disease is found in more than 90% of patients with trisomy 18, 50% of patients with trisomy 21, and 40% of those with Turner syndrome. Other genetic factors may have a role in congenital heart disease; e.g., certain types of VSDs (supracristal) are more common in Asian children. The risk of occurrence of congenital heart disease increases if a 1st-degree relative (parent or sibling) is affected.

A growing list of congenital heart lesions has been associated with specific chromosomal abnormalities, and several have even been linked to specific gene defects. Fluorescent in situ hybridization analysis allows clinicians rapid screening of suspected cases once a specific chromosomal abnormality has been identified, although clinical laboratory tests for specific gene defects are still uncommon. In addition, microarray genomic hybridization has identified previously unknown copy number variations (microdeletions or microduplications) in many patients with congenital heart disease and suspicion of a congenital anomaly syndrome. These variants are submicroscopic and thus not visible on routine chromosome analysis.

A well-characterized genetic cause of congenital heart disease is the deletion of a large region (1.5-3 Mb) of chromosome 22q11.2, known as the **DiGeorge critical region.** At least 30 genes have been mapped to the deleted region; *Tbx1,* a transcription factor involved in early outflow tract development is one gene that has been implicated as a possible cause of DiGeorge syndrome. The estimated prevalence of 22q11.2 deletions is 1/4,000 live births. Cardiac lesions associated with 22q11.2 deletions are most often seen in association with either the DiGeorge syndrome or the **Shprintzen (velocardiofacial) syndrome.** The acronym *CATCH 22* has been used to summarize the major components of these syndromes (cardiac defects, abnormal facies, thymic aplasia, cleft palate, and hypocalcemia). The specific cardiac anomalies are conotruncal defects (tetralogy of Fallot, truncus arteriosus, double-outlet right ventricle, subarterial VSD) and branchial arch defects (coarctation of the aorta, interrupted aortic arch, right aortic arch). Congenital airway anomalies such as tracheomalacia and bronchomalacia are sometimes present. Although the risk of recurrence is extremely low in the absence of a parental 22q11.2 deletion, it is 50% if 1 parent carries the deletion. More than 90% of patients with the clinical features of DiGeorge syndrome have a deletion at 22q11.2. A second genetic locus on the short arm of chromosome 10 (10p13p14) has also been identified, the deletion of which shares some, but not all, phenotypic characteristics with the 22q11.2 deletion; patients with del(10p) have an increased incidence of sensorineural hearing loss.

Other structural heart lesions that have been associated with specific chromosomal abnormalities include **familial secundum atrial septal defect** associated with **heart block** (the transcription factor Nkx2.5 on chromosome 5q35), familial atrial septal defect without heart block (the transcription factor GATA4), Alagille syndrome (Jagged1 on chromosome 20p12), and Williams syndrome (elastin on chromosome 7q11). Of interest, patients with VSDs and atrioventricular septal defects have been found to have multiple Nkx2.5 mutations in cells isolated from diseased heart tissues, but not from normal heart tissues or from circulating lymphocytes, indicating a potential role for somatic mutations leading to mosaicism in the pathogenesis of congenital heart defects. Tables 424-2 and 424-3 are a compilation of known genetic causes of congenital heart disease.

The most progress in identifying the genetic origin of cardiovascular disease has been made in the genetic cardiomyopathies, and in particular, **hypertrophic cardiomyopathy.** Mutations in several genes have been implicated, most of which encode protein components of the cardiac sarcomere, either components of the thick or thin fibers or associated regulatory subunits, although mutations in mitochondrial genes are increasingly recognized and play a larger role in those presenting with hypertrophic cardiomyopathy as young infants than in older children and adults. Mutations of the cardiac β-myosin heavy-chain gene (chromosome 14q1) and the myosin-binding protein C gene (chromosome 11q11) are the most common (see Table 424-4), with less-common mutations including the cardiac troponin T and I genes, α-tropomyosin, regulatory and essential myosin light chains, titin, and the α-myosin heavy chain. More than 200 mutations have

Table 424-2 Genetics of Congenital Heart Disease: Defects Associated with Syndromes

CARDIOVASCULAR DISEASE	CHROMOSOMAL LOCATION	GENE(S) IMPLICATED*	COMMON CARDIAC DEFECTS
DiGeorge syndrome, velocardiofacial syndrome	22q11.2, 11p13p14	*TBX1*	TOF, IAA, TA, VSD

*In many cases, mutation of a single gene has been closely linked to a specific cardiovascular disease, for example, by finding a high incidence of mutations or deletions of that gene in a large group of patients. These findings are often confirmed by studies in mice in which deletion or alteration of the gene induces a similar cardiac phenotype to the human disease. In others, mutation of a gene may increase the risk of cardiovascular disease, but with decreased penetrance, suggesting that modifier genes or environmental factors play a role. Finally, in some cases, gene mutations have only been identified in a small number of pedigrees, and confirmation awaits screening of larger numbers of patients.

been identified in these genes, and some patients may carry mutations in more than 1 gene. Routine clinical laboratory tests are now available for most of these mutations.

Progress has also been made in identifying the genetic basis of **dilated cardiomyopathy,** which is familial in 20-50% of cases. Autosomal dominant inheritance is most commonly encountered and, similar to hypertrophic cardiomyopathy, multiple genes have been identified (see Table 424-2). X-linked inheritance accounts for 5-10% of cases of familial dilated cardiomyopathy. Mutations in the dystrophin gene (chromosome Xp21) are the most common in this group. Mutations in the gene encoding *tafazzin* are associated with Barth syndrome and some cases of isolated non-compaction of the

left ventricle. Autosomal recessive inheritance is associated with a mutation in cardiac troponin I. Mitochondrial myopathies may be caused by mutations of enzymes of the electron transport chain encoded by nuclear DNA (in which inheritance will follow mendelian genetic patterns) or enzymes of fatty acid oxidation encoded by mitochondrial DNA (which is inherited solely from the mother). Table 424-4 is a compilation of the most common genetic causes of cardiomyopathy.

The genetic basis of **heritable arrhythmias,** most notably the **long Q-T syndromes,** has been linked to mutations of genes coding for subunits of cardiac potassium and sodium channels (see Table 424-2). Other heritable arrhythmias include arrhythmogenic right ventricular dysplasia, familial atrial fibrillation, familial complete heart block, and Brugada syndrome. Table 424-5 is a compilation of the most common genetic causes of arrhythmias.

Of all cases of congenital heart disease, 2-4% are associated with known environmental or adverse maternal conditions and teratogenic influences, including maternal diabetes mellitus, phenylketonuria, or systemic lupus erythematosus; congenital rubella syndrome; and maternal ingestion of drugs (lithium, ethanol, warfarin, thalidomide, antimetabolites, vitamin A derivatives, anticonvulsant agents) (see Table 422-2 in Chapter 422). Associated noncardiac malformations noted in identifiable syndromes may be seen in as many as 25% of patients with congenital heart disease.

Gender differences in the occurrence of specific cardiac lesions have been identified. Transposition of the great arteries and left-sided obstructive lesions are slightly more common in boys (≈65%), whereas atrial septal defect, VSD, PDA, and pulmonic stenosis are more common in girls. No racial differences in the occurrence of congenital heart lesions as a whole have been noted; for specific lesions such as transposition of the great arteries, a higher occurrence is seen in white infants.

GENETIC COUNSELING

Parents who have a child with congenital heart disease require counseling regarding the probability of a cardiac malformation occurring in subsequent children (see Chapter 77). With the exception of syndromes known to be caused by mutation of a single gene, most congenital heart disease is still relegated to a multifactorial inheritance pattern, which should result in a low risk of recurrence. As more genetic etiologies are identified, however, these risks will need constant updating. The incidence of congenital heart disease in the normal population is ≈0.8%, and this incidence increases to 2-6% for a second pregnancy after the birth of a child with congenital heart disease or if a parent is affected. This recurrence risk is highly dependent on the type of lesion in the first child. When two 1st-degree relatives have congenital heart disease, the risk for a subsequent child may reach 20-30%. When a second child is found to have congenital heart disease, it will tend to be of a similar

class as the lesion in their 1st-degree relative (conotruncal lesions, left-sided obstructive lesions, right-sided obstructive lesions, atrioventricular septation defects). The degree of severity may be variable, as is the presence of associated defects. Careful echocardiographic screening of 1st-degree relatives will often uncover mild forms of congenital heart disease that were clinically silent. For example, the incidence of bicuspid aortic valve is more than double (5% vs. 2% in the general population) in the relatives of children with left ventricular outflow obstructions (aortic stenosis, coarctation of the aorta, or hypoplastic left heart syndrome). Given the rapid advancements in the field of cardiovascular

genetics, consultation with a knowledgeable genetic counselor is the most reliable way of providing the family with up-to-date information regarding the risk of recurrence.

Fetal echocardiography improves the rate of detection of congenital heart lesions in high-risk patients (see Chapter 423). The resolution and accuracy of fetal echocardiography are excellent, but not perfect; families should be counseled that a normal fetal echocardiogram does not guarantee the absence of congenital heart disease. Congenital heart lesions may evolve in the course of the pregnancy; moderate aortic stenosis with a normal-sized left ventricle at 18 wk of gestation may evolve into aortic atresia with a hypoplastic left ventricle by 34 wk because of decreased flow through the atria, ventricle, and aorta in the latter half of gestation. This progression has prompted initial clinical trials of interventional treatment, such as fetal aortic balloon valvuloplasty, for the prevention of hypoplastic left heart syndrome (see Chapter 423.7).

The major factor in determining whether a **woman with congenital heart disease,** either unoperated or operated, will be able to carry a fetus to term is the mother's cardiovascular status. In the presence of a mild congenital heart defect or after successful repair of a more complex lesion, normal childbearing is likely. In a woman with palliated congenital heart disease or with poor cardiac function, however, the increased hemodynamic burden imposed by pregnancy may result in a significantly increased risk to both the mother and fetus. The incidence of spontaneous abortion in the presence of severe congenital heart disease is high, especially when the mother is cyanotic. The maternal risk in these situations is also high, and these pregnancies should be managed by an experienced perinatologist in conjunction with a cardiologist with expertise in adult congenital heart disease (see Chapter 434.1). It is important to discuss these risks, as well as various methods of birth control, with young women who have repaired or palliated congenital heart lesions. Antibiotic prophylaxis against endocarditis may also be indicated at the time of delivery.

Chapter 425

Evaluation and Screening of the Infant or Child with Congenital Heart Disease

Daniel Bernstein

The initial evaluation for suspected congenital heart disease involves a systematic approach with 3 major components. First, congenital cardiac defects can be divided into 2 major groups based on the presence or absence of cyanosis, which can be determined by physical examination aided by pulse oximetry. Second, these 2 groups can usually be further subdivided according to whether the chest radiograph shows evidence of increased, normal, or decreased pulmonary vascular markings. Finally, the electrocardiogram can be used to determine whether right, left, or biventricular hypertrophy exists. The character of the heart sounds and the presence and character of any murmurs further narrow the differential diagnosis. The final diagnosis is then confirmed by echocardiography, CT or MRI, or cardiac catheterization.

Multiple studies demonstrate the benefit of routine pulse oximetry screening for all newborns to detect unsuspected critical cyanotic congenital heart disease; lesions include hypoplastic left-heart syndrome, pulmonary atresia, tetralogy of Fallot, total anomalous pulmonary venous return, transposition of the great arteries, tricuspid atresia, truncus arteriosus, as well as neonatal coarctation of the aorta, and aortic arch hypoplasia/atresia. Many of these lesions are ductal dependent, and if the ductus arteriosus closes, severe cardiac decompensation will ensue. Such screening has been endorsed by the American Academy of Pediatrics, the American Heart Association, the American College of Cardiology and the March of Dimes, and recommended, although not mandated, by federal agencies such as Health and Human Services. Screening is performed between 24 and 48 hr of life and before discharge in asymptomatic newborns. A pulse oximetry saturation <90% in the right hand or either foot requires urgent echocardiography. A pulse oximetry saturation <95% in either location or a saturation difference >3% between the right hand and either foot is considered a positive test and should be repeated in an hour; if positive again, it should be repeated in another hour. If it remains positive, echocardiography is indicated. In addition, a careful reexamination of the pulses and blood pressure in the upper and lower extremity as well as a cardiac exam are indicated in children with an initial positive exam.

ACYANOTIC CONGENITAL HEART LESIONS

Acyanotic congenital heart lesions can be classified according to the predominant physiologic load that they place on the heart. Although many congenital heart lesions induce more than one physiologic disturbance, it is helpful to focus on the primary load abnormality for purposes of classification. The most common lesions are those that produce a volume load, and the most common of these are left-to-right shunt lesions. Atrioventricular (AV) valve regurgitation and some of the cardiomyopathies are other causes of increased volume load. The second major class of lesions causes an increase in pressure load, most commonly secondary to ventricular outflow obstruction (pulmonic or aortic valve stenosis) or narrowing of 1 of the great vessels (coarctation of the aorta). The chest radiograph and electrocardiogram are useful tools for differentiating between these major classes of volume and pressure overload lesions.

Lesions Resulting in Increased Volume Load

The most common lesions in this group are those that cause left-to-right shunting (see Chapter 426): atrial septal defect, ventricular septal defect (VSD), AV septal defects (AV canal), and patent ductus arteriosus. The pathophysiologic common denominator in this group is communication between the systemic and pulmonary sides of the circulation, which results in shunting of fully oxygenated blood back into the lungs. This shunt can be quantitated by calculating the ratio of pulmonary to systemic blood flow, or Qp : Qs. Thus, a 3 : 1 shunt implies 3 times the normal pulmonary blood flow.

The direction and magnitude of the shunt across such a communication depend on the size of the defect, the relative pulmonary and systemic pressure and vascular resistances, and the compliances of the 2 chambers connected by the defect. These factors are dynamic and may change dramatically with age: Intracardiac defects may grow smaller with time; pulmonary vascular resistance, which is high in the immediate newborn period, decreases to normal adult levels by several weeks of life; and chronic exposure of the pulmonary circulation to high pressure and blood flow results in a gradual increase in pulmonary vascular resistance (Eisenmenger physiology; see Chapter 433.2). Thus, a lesion such as a large VSD may be associated with little shunting and few symptoms during the initial weeks of life. When pulmonary vascular resistance declines in the next several weeks, the volume of the left-to-right shunt increases, and symptoms begin to appear.

The increased volume of blood in the lungs decreases pulmonary compliance and increases the work of breathing. Fluid leaks into the interstitial space and alveoli and causes pulmonary edema. The infant develops the symptoms we refer to as **heart failure,** such as tachypnea, tachycardia, sweating, chest retractions, nasal flaring, and wheezing. For children with large left-to-right shunts, the term *heart failure* is a misnomer, however; total left ventricular output is not decreased but is actually several times greater than normal, although much of this

output is ineffective because it returns directly to the lungs. To maintain this high level of left ventricular output, heart rate and stroke volume are increased, mediated by an increase in sympathetic nervous system activity. The increase in circulating catecholamines, combined with the increased work of breathing, results in an elevation in total body oxygen consumption, often beyond the oxygen transport ability of the circulation. Sympathetic activation leads to the additional symptoms of sweating and irritability and the imbalance between oxygen supply and demand lead to failure to thrive. Remodeling of the heart occurs, with predominantly chamber dilation and a lesser degree of hypertrophy. If left untreated, pulmonary vascular resistance eventually begins to rise and, by several years of age, the shunt volume will decrease and eventually reverse to right-to-left (Eisenmenger physiology; see Chapter 433.2).

Additional lesions that impose a volume load on the heart include regurgitant lesions (see Chapter 428) and the cardiomyopathies (see Chapter 439). Regurgitation through the AV valves is most commonly encountered in patients with partial or complete AV septal defects (AV canal, endocardial cushion defects). In these lesions, the combination of a left-to-right shunt with AV valve regurgitation increases the volume load on the heart and often leads to more severe symptoms. Isolated regurgitation through the tricuspid valve is seen in mild, moderate and severe forms of Ebstein anomaly (see Chapter 430.7). Regurgitation involving 1 of the semilunar (aortic or pulmonary) valves is usually also associated with some degree of stenosis; however, aortic regurgitation may be encountered in patients with a VSD directly under the aortic valve (supracristal VSD) and in patients with membranous subaortic stenosis.

In contrast to left-to-right shunts, in which intrinsic cardiac muscle function is generally either normal or increased, heart muscle function is decreased in the cardiomyopathies. **Cardiomyopathies** may affect systolic contractility or diastolic relaxation, or both. Decreased cardiac function results in increased atrial and ventricular filling pressure, and pulmonary edema occurs secondary to increased capillary pressure. Poor cardiac output leads to decreased organ blood flow, sympathetic activation, and the symptoms of poor perfusion and decreased urine output. The major causes of cardiomyopathy in infants and children include viral myocarditis, metabolic disorders, and genetic defects (see Chapter 439).

Lesions Resulting in Increased Pressure Load

The pathophysiologic common denominator of these lesions is an obstruction to normal blood flow. The most frequent are obstructions to ventricular outflow: valvular pulmonic stenosis, valvular aortic stenosis, and coarctation of the aorta (see Chapter 427). Less common are obstruction to ventricular inflow: tricuspid or mitral stenosis, cor triatriatum and obstruction of the pulmonary veins. Ventricular outflow obstruction can occur at the valve, below the valve (double-chambered right ventricle, subaortic membrane), or above it (branch pulmonary stenosis or supravalvular aortic stenosis). Unless the obstruction is severe, cardiac output will be maintained and the clinical symptoms of heart failure will be either subtle or absent. This compensation predominantly involves an increase in cardiac wall thickness (hypertrophy), but in later stages the affected chamber will begin to dilate and can progress to ventricular failure.

The clinical picture is different when obstruction to outflow is severe, which is usually encountered in the immediate newborn period. The infant may become critically ill within several hours of birth. Severe pulmonic stenosis in the newborn period (critical pulmonic stenosis) results in signs of right-sided heart failure (hepatomegaly, peripheral edema) as well as cyanosis from right-to-left shunting across the foramen ovale. Severe aortic stenosis in the newborn period (critical aortic stenosis) is characterized by signs of left-sided heart failure (pulmonary edema, poor perfusion) and right-sided failure (hepatomegaly, peripheral edema), and it may progress rapidly to total circulatory collapse. In older children, severe pulmonic stenosis leads to symptoms of right-sided heart failure, but usually not to cyanosis unless a pathway persists for right-to-left shunting (e.g., patency of the foramen ovale).

Coarctation of the aorta in older children and adolescents is usually manifested as upper body hypertension and diminished pulses in the lower extremities. In the immediate newborn period, the presentation of coarctation can range from decreased pulses in the lower extremities to total circulatory collapse, depending on the severity of the narrowing. However, the clinical presentation of coarctation may be delayed because of the presence of a patent ductus arteriosus. In these patients, the open aortic end of the ductus may serve as a conduit for blood flow to partially bypass the obstruction or for blood leaving the right ventricle to directly supply the descending aorta (as it did in the fetus). These infants then become symptomatic, often dramatically, when the ductus finally closes, usually within the 1st few wk of life.

CYANOTIC CONGENITAL HEART LESIONS

This group of congenital heart lesions can also be further divided according to pathophysiology: whether pulmonary blood flow is decreased (tetralogy of Fallot, pulmonary atresia with an intact septum, tricuspid atresia, total anomalous pulmonary venous return with obstruction) or increased (transposition of the great vessels, single ventricle, truncus arteriosus, total anomalous pulmonary venous return without obstruction). The chest radiograph is a valuable tool for initial differentiation between these 2 categories.

Cyanotic Lesions with Decreased Pulmonary Blood Flow

These lesions must include both an obstruction to pulmonary blood flow (at the tricuspid valve or right ventricular or pulmonary valve level) and a pathway by which systemic venous blood can shunt from right to left and enter the systemic circulation (via a patent foramen ovale, atrial septal defect, or VSD). Common lesions in this group include tricuspid atresia, tetralogy of Fallot, and various forms of single ventricle with pulmonary stenosis (see Chapter 430). In these lesions, the degree of cyanosis depends on the degree of obstruction to pulmonary blood flow. If the obstruction is mild, cyanosis may be absent at rest. These patients may have hypercyanotic ("tet") spells during conditions of stress. In contrast, if the obstruction is severe, pulmonary blood flow may be totally dependent on patency of the ductus arteriosus. When the ductus closes in the 1st few days of life, the neonate experiences profound hypoxemia and shock.

Cyanotic Lesions with Increased Pulmonary Blood Flow

This group of lesions is not associated with obstruction to pulmonary blood flow. Cyanosis is caused by either abnormal ventricular–arterial connections or total mixing of systemic venous and pulmonary venous blood within the heart (see Chapter 431). Transposition of the great vessels is the most common of the former group of lesions. In this condition, the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle. Systemic venous blood returning to the right atrium is pumped directly back to the body and oxygenated blood returning from the lungs to the left atrium is pumped back into the lungs. The persistence of fetal pathways (foramen ovale and ductus arteriosus) allows for a small degree of mixing in the immediate newborn period; when the ductus begins to close, these infants can become extremely cyanotic.

Total mixing lesions include cardiac defects with a common atrium or ventricle, total anomalous pulmonary venous return, and truncus arteriosus (see Chapter 431). In this group, deoxygenated systemic venous blood and oxygenated pulmonary venous blood mix completely in the heart and, as a result, oxygen saturation is equal in the pulmonary artery and aorta. If pulmonary blood flow is not obstructed, these infants have a combination of cyanosis and pulmonary overcirculation leading to heart failure. In contrast, if pulmonary stenosis is present, these infants may have cyanosis alone, similar to patients with tetralogy of Fallot.

Chapter **426**

Acyanotic Congenital Heart Disease: Left-to-Right Shunt Lesions

426.1 Atrial Septal Defect

Daniel Bernstein

Atrial septal defects (ASDs) can occur in any portion of the atrial septum (secundum, primum, or sinus venosus), depending on which embryonic septal structure has failed to develop normally (see Chapter 420). Less commonly, the atrial septum may be nearly absent, with the creation of a functional single atrium. Isolated secundum ASDs account for ≈7% of congenital heart defects. The majority of cases of ASD are sporadic; autosomal dominant inheritance does occur as part of the Holt-Oram syndrome (hypoplastic or absent thumbs, radii, triphalangism, phocomelia, 1st-degree heart block, ASD) or in families with secundum ASD and heart block (see Table 424-2 in Chapter 424).

An isolated valve-incompetent patent foramen ovale (PFO) is a common echocardiographic finding during infancy. It is usually of no hemodynamic significance and is not considered an ASD; a PFO may play an important role if other structural heart defects are present. If another cardiac anomaly is causing increased right atrial pressure (pulmonary stenosis or atresia, tricuspid valve abnormalities, right ventricular dysfunction), venous blood may shunt across the PFO into the left atrium with resultant cyanosis. Because of the anatomic structure of the PFO, left-to-right shunting is unusual outside the immediate newborn period. In the presence of a large volume load or a hypertensive left atrium (secondary to mitral stenosis), the foramen ovale may be sufficiently dilated to result in a significant atrial left-to-right shunt. A valve-competent but probe-PFO may be present in 15-30% of adults. An isolated PFO does not require surgical treatment, although it may be a risk for paradoxical (right to left) systemic embolization. Device closure of these defects has been considered in young adults with a history of thromboembolic stroke.

Bibliography is available at Expert Consult.

426.2 Ostium Secundum Defect

Daniel Bernstein

An ostium secundum defect in the region of the fossa ovalis is the most common form of ASD and is associated with structurally normal atrioventricular (AV) valves. Mitral valve prolapse has been described in association with this defect but is rarely an important clinical consideration. Secundum ASDs may be single or multiple (fenestrated atrial septum), and openings ≥2 cm in diameter are common in symptomatic older children. Large defects may extend inferiorly toward the inferior vena cava and ostium of the coronary sinus, superiorly toward the superior vena cava, or posteriorly. Females outnumber males 3:1 in incidence. Partial anomalous pulmonary venous return, most commonly of the right upper pulmonary vein, may be an associated lesion.

PATHOPHYSIOLOGY

The degree of left-to-right shunting is dependent on the size of the defect, the relative compliance of the right and left ventricles, and the relative vascular resistance in the pulmonary and systemic circulations. In large defects, a considerable shunt of oxygenated blood flows from the left to the right atrium (Fig. 426-1). This blood is added to the usual venous return to the right atrium and is pumped by the right ventricle to the lungs. With large defects, the ratio of pulmonary to systemic blood flow (Qp:Qs) is usually between 2:1 and 4:1. The paucity of symptoms in infants with ASDs is related to the structure of the right ventricle in early life when its muscular wall is thick and less compliant, thus limiting the left-to-right shunt. As the infant becomes older and pulmonary vascular resistance drops, the right ventricular wall becomes thinner and the left-to-right shunt across the ASD increases. The increased blood flow through the right side of the heart results in enlargement of the right atrium and ventricle and dilation of the pulmonary artery. The left atrium may also be enlarged, but the left ventricle and aorta are normal in size. Despite the large pulmonary blood flow, pulmonary arterial pressure is usually normal because of the absence of a high-pressure communication between the pulmonary and systemic circulations. Pulmonary vascular resistance remains low throughout childhood, although it may begin to increase in adulthood and may eventually result in reversal of the shunt and clinical cyanosis.

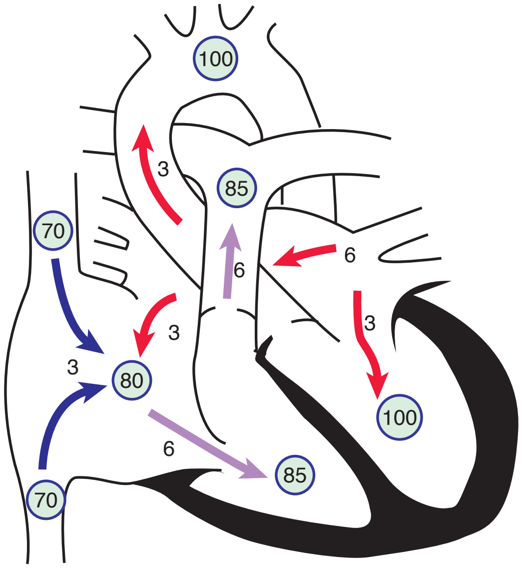

Figure 426-1 Physiology of atrial septal defect. *Circled numbers* represent oxygen saturation values. The *numbers next to the arrows* represent volumes of blood flow (in L/min/m^2). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp:Qs) of 2:1. Desaturated blood enters the right atrium from the vena cavae at a volume of 3 L/min/m^2 and mixes with an additional 3 L of fully saturated blood shunting left to right across the ASD; the result is an increase in oxygen saturation in the right atrium. Six liters of blood flows through the tricuspid valve and causes a mid-diastolic flow rumble. Oxygen saturation may be slightly higher in the right ventricle because of incomplete mixing at the atrial level. The full 6 L flows across the right ventricular outflow tract and causes a systolic ejection flow murmur. Six liters returns to the left atrium, with 3 L shunting left to right across the defect and 3 L crossing the mitral valve to be ejected by the left ventricle into the ascending aorta (normal cardiac output).

CLINICAL MANIFESTATIONS

A child with an ostium secundum ASD is most often asymptomatic; the lesion is often discovered inadvertently during physical examination. Even an extremely large secundum ASD rarely produces clinically evident heart failure in childhood. However, on closer evaluation, in younger children, subtle failure to thrive may be present; in older children varying degrees of exercise intolerance may be noted. Often, the degree of limitation may go unnoticed by the family until after surgical repair, when the child's growth or activity level increases

markedly. Platypnea (dyspnea on standing, relieved when supine) and orthodeoxia (desaturation on standing, relieved when supine) may occur when right to left shunting occurs through on ASD.

The physical findings of an ASD are usually characteristic but fairly subtle and require careful examination of the heart, with special attention to the heart sounds. Examination of the chest may reveal a mild left precordial bulge. A right ventricular systolic lift may be palpable at the left sternal border. Sometimes a pulmonic ejection click can be heard. In most patients with an ASD, the characteristic finding is that the 2nd heart sound is **widely split and fixed in its splitting** during all phases of respiration. Normally, the duration of right ventricular ejection varies with respiration, with inspiration increasing right ventricular volume and delaying closure of the pulmonary valve. With an ASD, right ventricular diastolic volume is constantly increased and the ejection time is prolonged throughout all phases of respiration. A systolic ejection murmur is heard; it is medium pitched, without harsh qualities, seldom accompanied by a thrill, and best heard at the left middle and upper sternal border. It is produced by the increased flow across the right ventricular outflow tract into the pulmonary artery, not by low-pressure flow across the ASD. A short, rumbling mid-diastolic murmur produced by the increased volume of blood flow across the tricuspid valve is often audible at the lower left sternal border. This finding, which may be subtle and is heard best with the bell of the stethoscope, usually indicates a Qp : Qs ratio of at least 2 : 1.

DIAGNOSIS

The chest roentgenogram shows varying degrees of enlargement of the right ventricle and atrium, depending on the size of the shunt. The pulmonary artery is enlarged, and pulmonary vascularity is increased. These signs vary and may not be conspicuous in mild cases. Cardiac enlargement is often best appreciated on the lateral view because the right ventricle protrudes anteriorly as its volume increases. The electrocardiogram shows volume overload of the right ventricle; the QRS axis may be normal or exhibit right axis deviation, and a minor right ventricular conduction delay (rsR′ pattern in the right precordial leads) may be present.

The echocardiogram shows findings characteristic of right ventricular volume overload, including an increased right ventricular end-diastolic dimension and flattening and abnormal motion of the ventricular septum (Fig. 426-2). A normal septum moves posteriorly during systole and anteriorly during diastole. With right ventricular overload and normal pulmonary vascular resistance, septal motion is either flattened or reversed—that is, anterior movement in systole. The location and size of the atrial defect are readily appreciated by 2-dimensional scanning, with a characteristic brightening of the echo image seen at the edge of the defect (T-artifact). The shunt is confirmed by pulsed and color flow Doppler. The normal entry of all pulmonary veins into the left atrium should be confirmed.

Patients with the classic features of a hemodynamically significant ASD on physical examination and chest radiography, in whom echocardiographic identification of an isolated secundum ASD is made, need not undergo diagnostic catheterization before repair, with the exception of an older patient, in whom pulmonary vascular resistance may be a concern. If pulmonary vascular disease is suspected, cardiac catheterization confirms the presence of the defect and allows measurement of the shunt ratio and pulmonary pressure and resistance.

If catheterization is performed, usually at the time of device closure (see below), the oxygen content of blood from the right atrium will be much higher than that from the superior vena cava. This feature is not specifically diagnostic because it may occur with partial anomalous pulmonary venous return to the right atrium, with a ventricular septal defect (VSD) in the presence of tricuspid insufficiency, with AV septal defects associated with left ventricular to right atrial shunts, and with aorta to right atrial communications (ruptured sinus of Valsalva aneurysm). Pressure in the right side of the heart is usually normal, but small to moderate pressure gradients (<25 mm Hg) may be measured across the right ventricular outflow tract because of functional stenosis related to excessive blood flow. In children and adolescents, the pulmonary vascular resistance is almost always normal. The shunt is

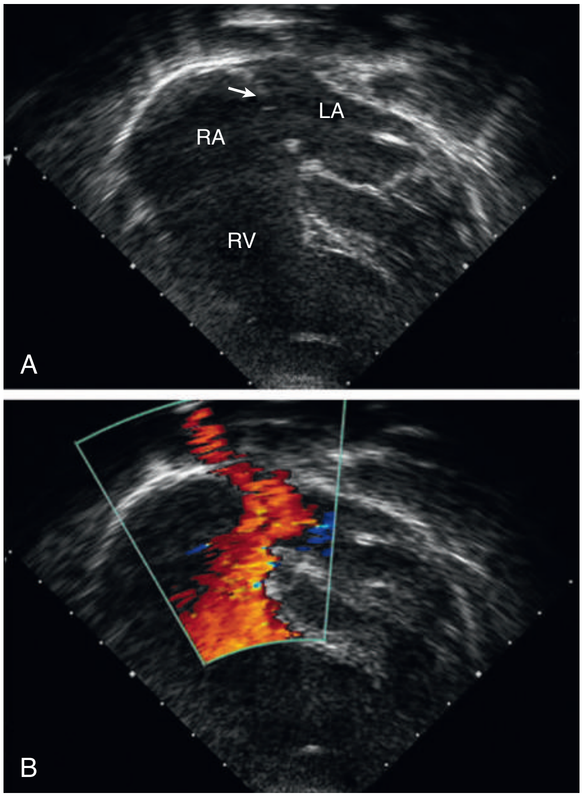

Figure 426-2 Echocardiographic findings in a secundum atrial septal defect. **A,** Two-dimensional echocardiogram (apical 4-chamber view) shows a moderate-sized secundum ASD *(arrow)*. **B,** Color flow Doppler imaging shows left-to-right shunting (the red color represents blood moving toward the ultrasound transducer and does not indicate the level of oxygenation of the blood). LA, left atrium; RA, right atrium; RV, right ventricle.

variable and depends on the size of the defect, but it may be of considerable volume (as high as 20 L/min/m^2). Cineangiography, performed with the catheter through the defect and in the right upper pulmonary vein, demonstrates the defect and the location of the right upper pulmonary venous drainage. Alternatively, pulmonary angiography demonstrates the defect on the levophase (return of contrast to the left side of the heart after passing through the lungs).

COMPLICATIONS

Secundum ASDs are usually isolated, although they may be associated with partial anomalous pulmonary venous return, pulmonary valvular stenosis, VSD, pulmonary artery branch stenosis, and persistent left superior vena cava, as well as mitral valve prolapse and insufficiency. Secundum ASDs are associated with the autosomal dominant Holt-Oram syndrome. The gene responsible for this syndrome, situated in the region 12q21-q22 of chromosome 12, is *TBX5*, a member of the T-box transcriptional family. A familial form of secundum ASD associated with AV conduction delay has been linked to mutations in another transcription factor, Nkx2.5. Patients with familial ASD without heart block may carry a mutation in the transcription factor GATA4, located on chromosome 8p22-23 (see Table 424-2 in Chapter 424).

TREATMENT

Transcatheter or surgical device closure is advised for all symptomatic patients and also for asymptomatic patients with a Qp : Qs ratio of at least 2 : 1 or those with right ventricular enlargement. The timing for elective closure is usually after the 1st yr and before entry into school. Closure carried out at open heart surgery is associated with a mortality rate of <1%. Repair is preferred during early childhood because

surgical mortality and morbidity are significantly greater in adulthood; the long-term risk of arrhythmia is also greater after ASD repair in adults. For most patients, the *procedure of choice* is percutaneous catheter device closure using an atrial septal occlusion device, implanted transvenously in the cardiac catheterization laboratory (Fig. 426-3). The results are excellent and patients are discharged the following day. With the latest generation of devices, the incidence of serious complications such as device erosion is 0.1% and can be decreased by identifying high-risk patients such as those with a deficient rim of septum around the device. Echocardiography can usually determine whether a patient is a good candidate for device closure. In patients with small secundum ASDs and minimal left-to-right shunts without right ventricular enlargement, the consensus is that closure is not required. It is unclear at present whether the persistence of a small ASD into adulthood increases the risk for stroke enough to warrant prophylactic closure of all these defects.

PROGNOSIS

Small- to moderate-sized ASDs detected in term infants may close spontaneously. Secundum ASDs are well tolerated during childhood, and symptoms do not usually appear until the 3rd decade or later. Pulmonary hypertension, atrial dysrhythmias, tricuspid or mitral insufficiency, and heart failure are late manifestations; these symptoms may initially appear during the increased volume load of pregnancy. Infective endocarditis is extremely rare, and antibiotic prophylaxis for isolated secundum ASDs is not recommended.

The results after surgical or device closure in children with moderate to large shunts are excellent. Symptoms disappear rapidly, and growth is frequently enhanced. Heart size decreases to normal, and the electrocardiogram shows decreased right ventricular forces. Late right-heart failure and arrhythmias are less frequent in patients who have had early repair, becoming more common in patients who undergo surgery after 20 yr of age. Although early and midterm results with device closure are excellent, the long-term effects are not yet known. Reports of resolution of migraine headaches in patients after device closure of ASD or PFO are intriguing, suggesting a possible thromboembolic etiology; there are also paradoxical reports of patients whose migraines began or worsened after placement of one of these devices.

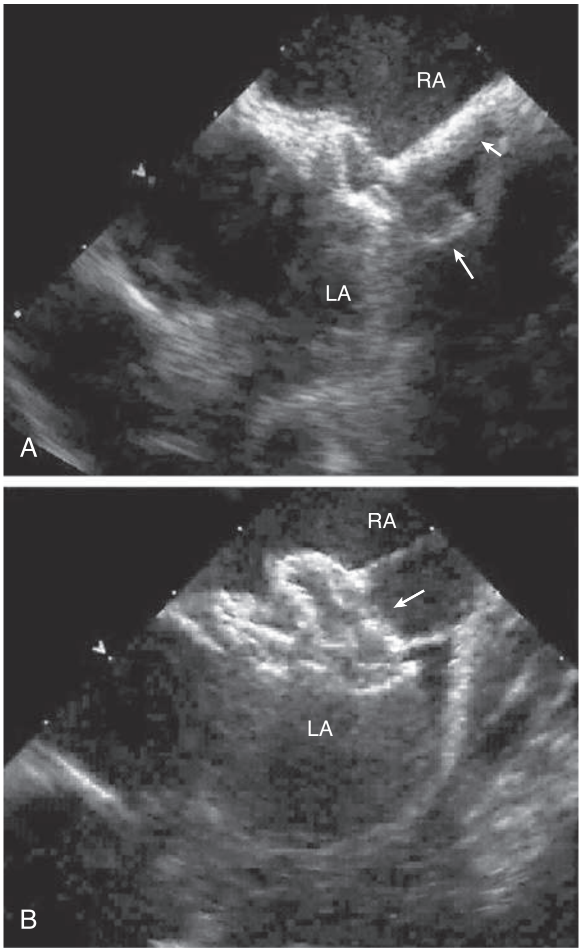

Figure 426-3 Intravascular ultrasound imaging of transcatheter occlusion of an atrial septal defect. **A,** A catheter *(small arrow)* has been advanced across the atrial defect, and the left-sided disk of the device *(large arrow)* has been extruded from the sheath into the left atrium *(LA)*. **B,** The right atrial disk *(arrow)* has now been extruded into the right atrium *(RA)*. The 2 halves of the device are then locked together and the catheter detached from the occluder device and removed.

426.3 Sinus Venosus Atrial Septal Defect

Daniel Bernstein

A sinus venosus ASD is situated in the upper part of the atrial septum in close relation to the entry of the superior vena cava. Often, 1 or more pulmonary veins (usually from the right lung) drain anomalously into the superior vena cava. The superior vena cava sometimes straddles the defect; in this case, some systemic venous blood enters the left atrium, but only rarely does it cause clinically evident cyanosis. The hemodynamic disturbance, clinical picture, electrocardiogram, and roentgenogram are similar to those seen in secundum ASD. The diagnosis can usually be made by 2-dimensional echocardiography. If there are questions regarding pulmonary venous drainage, cardiac CT or MRI is usually diagnostic. Cardiac catheterization is rarely required, with the exception being in adult patients where assessment of pulmonary vascular resistance may be important. Anatomic correction generally requires the insertion of a patch to close the defect while incorporating the entry of anomalous veins into the left atrium. If the anomalous vein drains high in the superior vena cava, the vein can be left intact and the ASD closed to incorporate the mouth of the superior vena cava into the left atrium. The superior vena cava proximal to the venous entrance is then detached and anastomosed directly to the right atrium. This procedure avoids direct suturing of the pulmonary vein with less chance of future stenosis. Surgical results are generally excellent. Rarely, sinus venosus defects involve the inferior vena cava.

426.4 Partial Anomalous Pulmonary Venous Return

Daniel Bernstein

One or several pulmonary veins may return anomalously to the superior or inferior vena cava, the right atrium, or the coronary sinus and produce a left-to-right shunt of oxygenated blood. Partial anomalous pulmonary venous return usually involves some or all of the veins from only 1 lung, more often the right one. When an associated ASD is present, it is generally of the sinus venosus type, although can be of the secundum type (see Chapters 426.2 and 426.3). When an ASD is detected by echocardiography, one must always search for associated partial anomalous pulmonary venous return. The history, physical signs, and electrocardiographic and radiologic findings are indistinguishable from those of an isolated ostium secundum ASD. Occasionally, an anomalous vein draining into the inferior vena cava is visible on chest radiography as a crescentic shadow of vascular density along the right border of the cardiac silhouette **(scimitar syndrome);** in these cases, an ASD is not usually present, but **pulmonary sequestration or ipsilateral lung hypoplasia** and anomalous arterial supply to that lobe are common findings. Total anomalous pulmonary venous return is a cyanotic lesion and is discussed in Chapter 431.7. Echocardiography generally confirms the diagnosis. MRI and CT are also useful if there

is a question regarding pulmonary venous drainage or in cases of scimitar syndrome. If cardiac catheterization is performed, the presence of anomalous pulmonary veins is demonstrated by selective pulmonary arteriography and anomalous pulmonary arterial supply to the right lung is demonstrated by descending aortography.

The prognosis is excellent, similar to that for ostium secundum ASDs. When a large left-to-right shunt is present, surgical repair is performed. The associated ASD should be closed in such a way that pulmonary venous return is directed to the left atrium. A single anomalous pulmonary vein without an atrial communication may be difficult to redirect to the left atrium; if the shunt is small, it may be left unoperated.

426.5 Atrioventricular Septal Defects (Ostium Primum and Atrioventricular Canal or Endocardial Cushion Defects)

Daniel Bernstein

The abnormalities encompassed by AV septal defects are grouped together because they represent a spectrum of a basic embryologic abnormality, a deficiency of the AV septum. An **ostium primum** defect is situated in the lower portion of the atrial septum and overlies the mitral and tricuspid valves. In most instances, a **cleft** in the **anterior leaflet** of the **mitral valve** is also noted. The tricuspid valve is usually functionally normal, although some anatomic abnormality of the septal leaflet is present. The ventricular septum is intact.

An **AV septal defect,** also known as an **AV canal defect** or an **endocardial cushion defect**, consists of contiguous atrial and VSDs with markedly abnormal AV valves. The severity of the valve abnormalities varies considerably; in the complete form of AV septal defect, a single AV valve is common to both ventricles and consists of an anterior and a posterior bridging leaflet related to the ventricular septum, with a lateral leaflet in each ventricle. The lesion is common in children with **Down syndrome**.

Transitional varieties of these defects also occur and include ostium primum defects with clefts in the anterior mitral and septal tricuspid valve leaflets and small VSDs, and, less commonly, ostium primum defects with normal AV valves. In some patients, the atrial septum is intact, but an inlet VSD is similar to that found in the full AV septal defect. Sometimes AV septal defects are associated with varying degrees of hypoplasia of one of the ventricles, known as either *left-* or *right-dominant atrioventricular septal defect*. If the affected ventricular chamber is too small to establish a 2-ventricle circulation, then surgical palliation, aiming for an eventual Fontan procedure, is performed (see Chapters 430.4 and 431.10).

PATHOPHYSIOLOGY

The basic abnormality in patients with ostium primum defects is the combination of a left-to-right shunt across the atrial defect and mitral (or occasionally tricuspid) insufficiency. The shunt is usually moderate to large, the degree of mitral insufficiency is generally mild to moderate, and pulmonary arterial pressure is typically normal or only mildly increased. The physiology of this lesion is, therefore, similar to that of an ostium secundum ASD.

In complete AV septal defects, the left-to-right shunt occurs at both the atrial and ventricular levels (Fig. 426-4). Additional shunting may occur directly from the left ventricle to the right atrium because of absence of the AV septum. Pulmonary hypertension and an early tendency to increase pulmonary vascular resistance are common. AV valvular insufficiency increases the volume load on one or both ventricles. If the defect is large enough, some right-to-left shunting may also occur at both the atrial and ventricular levels and lead to mild arterial desaturation. With time, progressive pulmonary vascular disease increases the right-to-left shunt so that clinical cyanosis develops (Eisenmenger physiology; see Chapter 433.2).

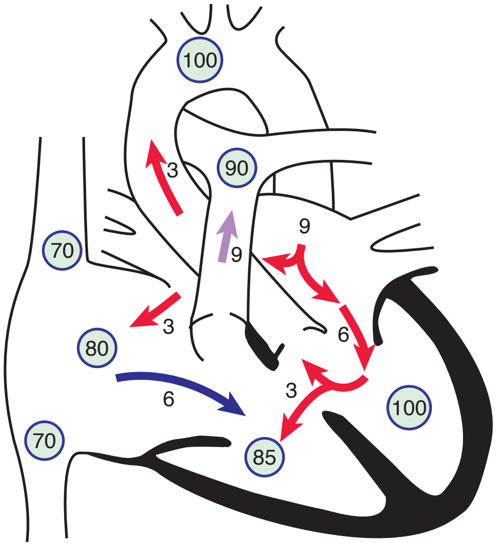

Figure 426-4 Physiology of atrioventricular septal defect. *Circled numbers* represent oxygen saturation values. The *numbers next to the arrows* represent volumes of blood flow (in L/min/m^2). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp : Qs) of 3 : 1. Desaturated blood enters the right atrium from the vena cavae at a volume of 3 L/min/m^2 and mixes with 3 L of fully saturated blood shunting left to right across the atrial septal defect; the result is an increase in oxygen saturation in the right atrium. Six liters of blood flows through the right side of the common AV valve, joined by an additional 3 L of saturated blood shunting left to right at the ventricular level, further increasing oxygen saturation in the right ventricle. The full 9 L flows across the right ventricular outflow tract into the lungs. Nine liters returns to the left atrium, with 3 L shunting left to right across the defect and 6 L crossing the left side of the common AV valve and causing a mid-diastolic flow rumble. Three liters of this volume shunts left to right across the VSD, and 3 L is ejected into the ascending aorta (normal cardiac output).

CLINICAL MANIFESTATIONS

Many children with ostium primum defects are asymptomatic, and the anomaly is discovered during a general physical examination. In patients with moderate shunts and mild mitral insufficiency, the physical signs are similar to those of the secundum ASD, but with an additional apical holosystolic murmur caused by mitral insufficiency.

A history of exercise intolerance, easy fatigability, and recurrent pneumonia may be obtained, especially in infants with large left-to-right shunts and severe mitral insufficiency. In these patients, cardiac enlargement is moderate or marked, and the precordium is hyperdynamic. Auscultatory signs produced by the left-to-right shunt include a normal or accentuated 1st heart sound; wide, fixed splitting of the 2nd sound; a pulmonary systolic ejection murmur sometimes preceded by a click; and a low-pitched, mid-diastolic rumbling murmur at the lower left sternal edge or apex, or both, as a result of increased flow through the AV valves. Mitral insufficiency may be manifested by a harsh (occasionally very high pitched) apical holosystolic murmur that radiates to the left axilla.

With complete AV septal defects, heart failure and intercurrent pulmonary infection usually appear in infancy. The liver is enlarged and the infant shows signs of failure to thrive. Cardiac enlargement is moderate to marked, and a systolic thrill is frequently palpable at the lower left sternal border. A precordial bulge and lift may be present as well. The 1st heart sound is normal or accentuated. The 2nd heart sound is widely split if the pulmonary flow is massive. A low-pitched, mid-diastolic rumbling murmur is audible at the lower left sternal border, and a pulmonary systolic ejection murmur is produced by the large pulmonary flow. The harsh apical holosystolic murmur of mitral insufficiency may also be present.

DIAGNOSIS

Chest radiographs of children with complete AV septal defects often show moderate to severe cardiac enlargement caused by the prominence of both ventricles and atria. The pulmonary artery is large, and pulmonary vascularity is increased.

The electrocardiogram in patients with a complete AV septal defect is distinctive. The principal abnormalities are (1) superior orientation of the mean frontal QRS axis with left axis deviation to the left upper or right upper quadrant, (2) counterclockwise inscription of the superiorly oriented QRS vector loop (often manifest by a Q wave in leads I and aVL), (3) signs of biventricular hypertrophy or isolated right ventricular hypertrophy, (4) right ventricular conduction delay (rSR′ pattern in leads V_3R and V_1), (5) normal or tall P waves, and (6) occasional prolongation of the P-R interval (Fig. 426-5).

The echocardiogram (Fig. 426-6) is diagnostic and shows signs of right ventricular enlargement with encroachment of the mitral valve echo on the left ventricular outflow tract; the abnormally low position of the AV valves results in a "gooseneck" deformity of the left ventricular outflow tract. In normal hearts, the tricuspid valve inserts slightly more toward the apex than the mitral valve does. In AV septal defects, both valves insert at the same level because of absence of the AV septum. In complete AV septal defects, the ventricular septum is also deficient and the common AV valve is readily appreciated. Pulsed and color flow Doppler echocardiography will demonstrate left-to-right shunting at the atrial, ventricular, or left ventricular to right atrial levels and can be used to semiquantitate the degree of AV valve insufficiency. Echocardiography is useful for determining the insertion points of the chordae of the common AV valve and for evaluating the presence of associated lesions such as patent ductus arteriosus (PDA) or coarctation of the aorta.

Cardiac catheterization and angiocardiography is rarely required to confirm the diagnosis unless pulmonary vascular disease is suspected, such as in a patient in whom diagnosis has been delayed beyond early infancy, especially in those with Down syndrome in whom the development of pulmonary vascular disease may be more rapid. Catheterization demonstrates the magnitude of the left-to-right shunt, the degree of elevation of pulmonary vascular resistance, and the severity of insufficiency of the common AV valve. By oximetry, the shunt is usually demonstrable at both the atrial and ventricular levels. Arterial oxygen saturation is normal or only mildly reduced unless severe pulmonary vascular disease is present. Children with ostium primum defects generally have normal or only moderately elevated pulmonary arterial pressure. Conversely, complete AV septal defects are associated with right ventricular and pulmonary hypertension and, in older patients, with increased pulmonary vascular resistance (see Chapter 433.2).

Selective left ventriculography will demonstrate deformity of the mitral or common AV valve and the distortion of the left ventricular outflow tract caused by this valve (gooseneck deformity). The abnormal anterior leaflet of the mitral valve is serrated, and mitral insufficiency is noted, usually with regurgitation of blood into both the left and right atria. Direct shunting of blood from the left ventricle to the right atrium may also be demonstrated.

TREATMENT

Ostium primum defects are approached surgically from an incision in the right atrium. The cleft in the mitral valve is located through the atrial defect and is repaired by direct suture. The defect in the atrial septum is usually closed by insertion of a patch prosthesis. The surgical mortality rate for ostium primum defects is very low.

Surgical treatment of complete AV septal defects is more difficult, although still highly successful. The postoperative course may be prolonged in infants with severe cardiac failure and in those with pulmonary hypertension. Because of the risk of **pulmonary vascular disease** developing as early as 6-12 mo of age, surgical intervention must be performed during infancy. Full correction of these defects can be readily accomplished in infancy; palliation with pulmonary arterial banding, once more common, is reserved for the small subset of patients who have other associated lesions that make early corrective surgery too risky. The atrial and ventricular defects are patched and the AV valves reconstructed. Complications include surgically induced heart block requiring placement of a permanent pacemaker, excessive narrowing of the left ventricular outflow tract requiring surgical revision, and residual tricuspid or mitral regurgitation, which long-term can require replacement with a prosthetic valve.

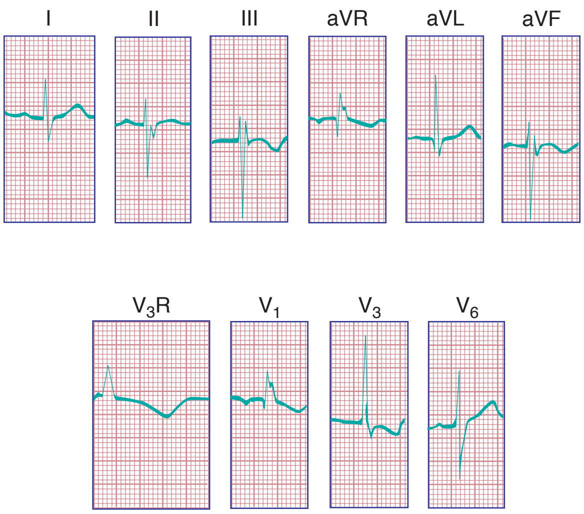

Figure 426-5 **Electrocardiogram from a child with an atrioventricular septal defect.** Note the QRS axis of –60 degrees and the right ventricular conduction delay with an RSR′ pattern in V_1 and V_3R (V_3R paper speed = 50 mm/sec).

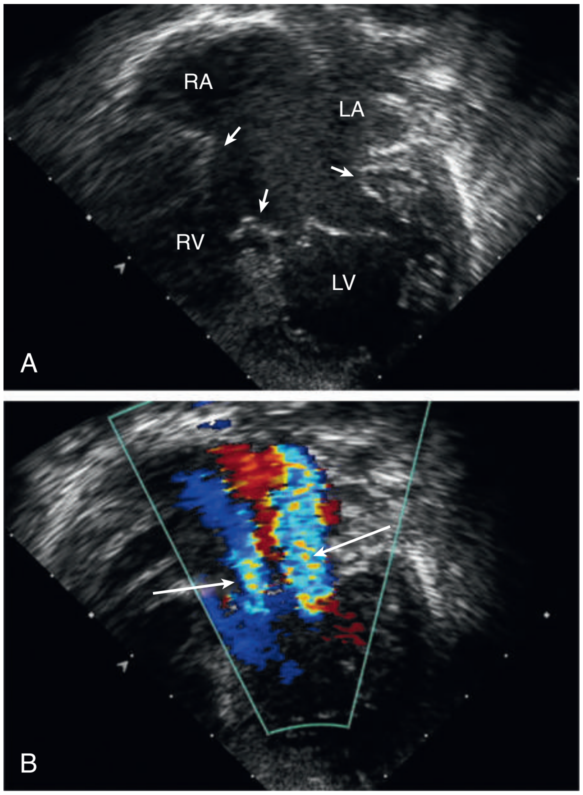

Figure 426-6 Echocardiogram of an atrioventricular septal defect. **A,** Subcostal 4-chamber view demonstrating the common atrioventricular valve *(arrows)* spanning the atrial and ventricular septal defects. **B,** Doppler imaging shows 2 jets of regurgitation through the left side of the common atrioventricular valve *(arrows)*. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

PROGNOSIS

The prognosis for unrepaired complete AV septal defects depends on the magnitude of the left-to-right shunt, the degree of elevation of pulmonary vascular resistance, and the severity of AV valve insufficiency. Death from cardiac failure during infancy used to be frequent before the advent of early corrective surgery. In patients who survived without surgery, pulmonary vascular obstructive disease usually developed. Most patients with ostium primum defects and minimal AV valve involvement are asymptomatic or have only minor, nonprogressive symptoms until they reach the 3rd-4th decade of life, similar to the course of patients with secundum ASDs. Late postoperative complications include atrial arrhythmias and heart block, progressive narrowing of the left ventricular outflow tract requiring surgical revision, and eventual worsening of AV valve regurgitation (usually on the left side) requiring replacement with a prosthetic valve.

Bibliography is available at Expert Consult.

426.6 Ventricular Septal Defect

Daniel Bernstein

VSD is the most common cardiac malformation and accounts for 25% of congenital heart disease. Defects may occur in any portion of the ventricular septum, but most are of the membranous type. These defects are in a posteroinferior position, anterior to the septal leaflet of the tricuspid valve. VSDs between the crista supraventricularis and the papillary muscle of the conus may be associated with pulmonary stenosis and other manifestations of tetralogy of Fallot (see Chapter 430.1). VSDs superior to the crista supraventricularis (supracristal) are less common; they are found just beneath the pulmonary valve and may impinge on an aortic sinus and cause aortic insufficiency. VSDs in the midportion or apical region of the ventricular septum are muscular in type and may be single or multiple (Swiss cheese septum).

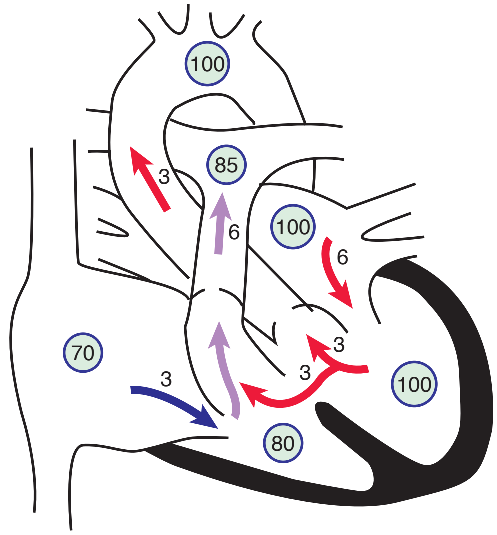

Figure 426-7 Physiology of a large ventricular septal defect. *Circled numbers* represent oxygen saturation values. The *numbers next to the arrows* represent volumes of blood flow (in L/min/m^2). This illustration shows a hypothetical patient with a pulmonary-to-systemic blood flow ratio (Qp:Qs) of 2:1. Desaturated blood enters the right atrium from the vena cava at a volume of 3 L/min/m^2 and flows across the tricuspid valve. An additional 3 L of blood shunts left to right across the VSD, the result being an increase in oxygen saturation in the right ventricle. Six liters of blood is ejected into the lungs. Pulmonary arterial saturation may be further increased because of incomplete mixing at right ventricular level. Six liters returns to the left atrium, crosses the mitral valve, and causes a mid-diastolic flow rumble. Three liters of this volume shunts left to right across the VSD, and 3 L is ejected into the ascending aorta (normal cardiac output).

PATHOPHYSIOLOGY

The physical size of the VSD is a major, but not the only, determinant of the size of the left-to-right shunt. The level of pulmonary vascular resistance in relation to systemic vascular resistance also determines the shunt's magnitude. When a small communication is present (usually <5 mm), the VSD is pressure **restrictive**, meaning that right ventricular pressure is normal. The higher pressure in the left ventricle drives the shunt left to right and the size of the defect limits the magnitude of the shunt. In large **nonrestrictive VSDs** (usually >10 mm), right and left ventricular pressures are equalized. In these defects, the direction of shunting and the shunt magnitude are determined by the ratio of pulmonary to systemic vascular resistance (Fig. 426-7).

After birth in patients with a large VSD, pulmonary vascular resistance may remain elevated, delaying the normal postnatal decrease, and thus the size of the left-to-right shunt may initially be limited. Because of normal involution of the media of small pulmonary arterioles, pulmonary vascular resistance begins to fall in the 1st few wk after birth and the size of the left-to-right shunt increases. Eventually, a large left-to-right shunt develops, and clinical symptoms become apparent. In most cases during early infancy, pulmonary vascular resistance is only slightly elevated, and the major contribution to pulmonary hypertension is the large communication allowing exposure of the pulmonary circulation to systemic pressure and the large pulmonary blood flow. With continued exposure of the pulmonary vascular bed to high systolic pressure and high flow, pulmonary vascular obstructive disease eventually develops. When the ratio of pulmonary to systemic resistance approaches 1:1, the shunt becomes bidirectional, signs of heart failure abate, and the patient begins to show signs of cyanosis (Eisenmenger physiology; see Chapter 433.2). In rare infants with a large VSD, usually those with Down syndrome, pulmonary vascular resistance never decreases, and symptoms may remain minimal until Eisenmenger physiology becomes evident.

The magnitude of intracardiac shunts is usually described by the Qp:Qs ratio. If the left-to-right shunt is small (Qp:Qs < 1.5:1), the cardiac chambers are not appreciably enlarged and the pulmonary vascular bed is probably normal. If the shunt is large (Qp:Qs > 2:1), left atrial and ventricular volume overload occurs, as does right ventricular and pulmonary arterial hypertension. The main pulmonary artery, left atrium, and left ventricle are enlarged.

CLINICAL MANIFESTATIONS

The clinical findings of patients with a VSD vary according to the size of the defect and pulmonary blood flow and pressure. Small VSDs with trivial left-to-right shunts and normal pulmonary arterial pressure are the most common. These patients are asymptomatic, and the cardiac lesion is usually found during routine physical examination. Characteristically, a loud, harsh, or blowing holosystolic murmur is present and heard best over the lower left sternal border, and it is frequently accompanied by a thrill. In a few instances, the murmur ends before the 2nd sound, presumably because of closure of the defect during late systole. A short, harsh systolic murmur localized to the apex in a neonate is often a sign of a tiny VSD in the apical muscular septum. In premature infants, the murmur may be heard early because pulmonary vascular resistance decreases more rapidly.

Large VSDs with excessive pulmonary blood flow and pulmonary hypertension are responsible for dyspnea, feeding difficulties, poor growth, profuse perspiration, recurrent pulmonary infections, and cardiac failure in early infancy. Cyanosis is usually absent, but duskiness is sometimes noted during infections or crying. Prominence of the left precordium is common, as are a palpable parasternal lift, a laterally displaced apical impulse and apical thrust, and a systolic thrill. The holosystolic murmur of a large VSD is generally less harsh than that of a small VSD and more blowing in nature because of the absence of a significant pressure gradient across the defect. It is even less likely to be prominent in the newborn period. The pulmonic component of

the 2nd heart sound may be increased as a result of pulmonary hypertension. The presence of a mid-diastolic, low-pitched rumble at the apex is caused by increased blood flow across the mitral valve and usually indicates a Qp : Qs ratio of ≥2 : 1. This murmur is best appreciated with the bell of the stethoscope.

DIAGNOSIS

In patients with small VSDs, the chest x-ray is usually normal, although minimal cardiomegaly and a borderline increase in pulmonary vasculature may be observed. The electrocardiogram is generally normal but may suggest left ventricular hypertrophy. The presence of right ventricular hypertrophy is a warning that the defect is not small and that the patient has pulmonary hypertension or an associated lesion such as pulmonic stenosis. In large VSDs, the chest x-ray shows gross cardiomegaly with prominence of both ventricles, the left atrium, and the pulmonary artery (Fig. 426-8). Pulmonary vascular markings are increased, and frank pulmonary edema, including pleural effusions, may be present. The electrocardiogram shows biventricular hypertrophy; P waves may be notched or peaked.

The 2-dimensional echocardiogram (Fig. 426-9) shows the position and size of the VSD. In small defects, especially those of the muscular septum, the defect itself may be difficult to image and is visualized only by color Doppler examination. In defects of the **membranous septum,** a thin membrane (called a **ventricular septal aneurysm** but consisting of tricuspid valve tissue) can partially cover the defect and limit the volume of the left-to-right shunt. Echocardiography is also useful for estimating shunt size by examining the degree of volume overload of the left atrium and left ventricle; in the absence of associated lesions, the extent of their increased dimensions is a good reflection of the size of the left-to-right shunt. Pulsed Doppler examination shows whether the VSD is pressure restrictive by calculating the pressure gradient across the defect. Such calculation allows an estimation of right ventricular pressure and helps determine whether the patient is at risk for the development of early pulmonary vascular disease. The echocardiogram can also be useful to determine the presence of aortic valve insufficiency or aortic leaflet prolapse in the case of supracristal VSDs.

The hemodynamics of a VSD can also be demonstrated by cardiac catheterization, although catheterization is today performed only when laboratory data do not fit well with the clinical findings or when pulmonary vascular disease is suspected. Oximetry demonstrates increased oxygen content in the right ventricle; because some defects eject blood almost directly into the pulmonary artery (streaming), the full magnitude of the oxygen saturation increase is occasionally apparent only when pulmonary arterial blood is sampled. Small, restrictive VSDs are associated with normal right-heart pressures and pulmonary vascular resistance. Large, nonrestrictive VSDs are associated with equal or nearly equal pulmonary and systemic systolic pressure and variable elevations in pulmonary vascular resistance. Pulmonary blood flow may be 2-4 times systemic blood flow. In patients with such **"hyperdynamic pulmonary hypertension,"** pulmonary vascular resistance is only minimally elevated because resistance is equal to pressure divided by flow. However, if left untreated until Eisenmenger syndrome is present, pulmonary artery systolic and diastolic pressure will be elevated but the degree of left-to-right shunting minimal. In these cases, desaturation of blood in the left ventricle is usually encountered.

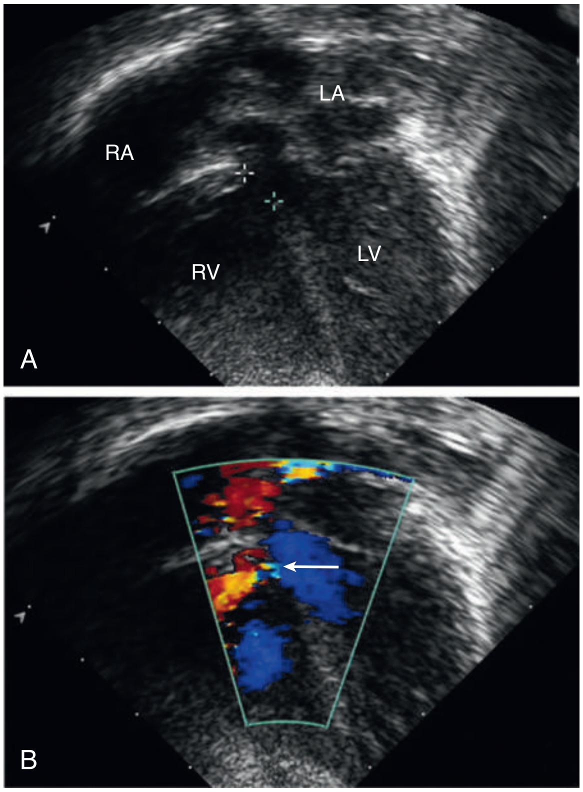

Figure 426-9 Echocardiogram in a patient with a perimembranous ventricular septal defect. **A,** Apical 4-chamber view showing the location of the defect (outlined between 2 *crosshatches*) beneath the aortic valve. **B,** Color Doppler imaging shows the left-to-right shunt *(arrow)* through the defect (the red color represents blood moving toward the ultrasound transducer and does not indicate the level of oxygenation of the blood). LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

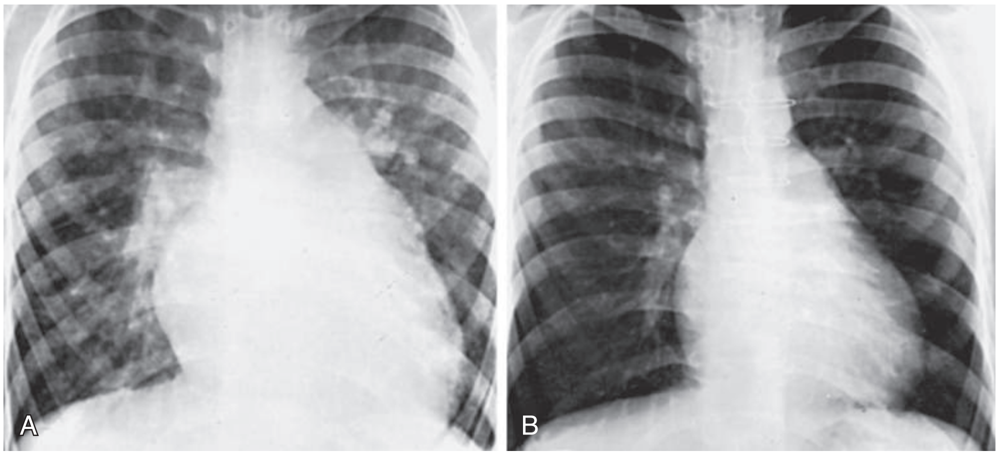

Figure 426-8 **A,** Preoperative radiograph in a patient with a ventricular septal defect with a large left-to-right shunt and pulmonary hypertension. Significant cardiomegaly, prominence of the pulmonary arterial trunk, and pulmonary overcirculation are evident. **B,** Three years after surgical closure of the defect, heart size is markedly decreased, and the pulmonary vasculature is normal.

The size, location, and number of ventricular defects can be demonstrated by left ventriculography. Contrast medium passes across the defect or defects to opacify the right ventricle and pulmonary artery. Administration of 100% oxygen with and without nitric oxide can be used to determine whether the pulmonary vascular resistance, if elevated, is still reactive and therefore more likely to drop after surgical repair.

TREATMENT

The natural course of a VSD depends to a large degree on the size of the defect. A significant number (30-50%) of small defects close spontaneously, most frequently during the 1st 2 yr of life. Small muscular VSDs are more likely to close (up to 80%) than membranous VSDs (up to 35%). The vast majority of defects that close do so before the age of 4 yr, although spontaneous closure has been reported in adults. VSDs that close often have ventricular septal aneurysm (accessory tricuspid valve) tissue that limits the magnitude of the shunt. Most children with small restrictive defects remain asymptomatic, without evidence of an increase in heart size, pulmonary arterial pressure, or resistance; a long-term risk is infective endocarditis. Some long-term studies of adults with unoperated small VSDs show an increased incidence of arrhythmia, subaortic stenosis, and exercise intolerance. Guidelines from the Council on Cardiovascular Disease in the Young of the American Heart Association state that an isolated, small, hemodynamically insignificant VSD is not an indication for surgery. However, the declining risk of open heart surgery has led some to suggest that all VSDs be closed electively by mid-childhood.

It is less common for moderate or large VSDs to close spontaneously, although even defects large enough to result in heart failure may become smaller and up to 8% may close completely. More commonly, infants with large defects have repeated episodes of respiratory infection and heart failure despite optimal medical management. Heart failure may be manifested in many of these infants primarily as failure to thrive. Pulmonary hypertension occurs as a result of high pulmonary blood flow. These patients are at risk for pulmonary vascular disease if the defect is not repaired during early infancy.

Patients with VSD are also at risk for the development of aortic valve regurgitation, the greatest risk occurring in patients with a supracristal VSD (see Chapter 426.7). A small number of patients with VSD develop **acquired infundibular pulmonary stenosis,** which then protects the pulmonary circulation from the short-term effects of pulmonary overcirculation and the long-term effects of pulmonary vascular disease. In these patients, the clinical picture changes from that of a VSD with a large left-to-right shunt to a VSD with pulmonary stenosis. The shunt may diminish in size, become balanced, or even become a net right-to-left shunt. These patients must be carefully distinguished from those in whom an Eisenmenger physiology develops (see Chapter 433.2).

In patients with small VSDs, parents should be reassured of the relatively benign nature of the lesion, and the child should be encouraged to live a normal life, with no restrictions on physical activity. Surgical repair is not recommended. As protection against infective endocarditis, the integrity of primary and permanent teeth should be carefully maintained; with the latest revision of the American Heart Association guidelines, antibiotic prophylaxis is no longer recommended for dental visits or surgical procedures (see Chapter 437). These patients can be monitored by a combination of clinical examination and noninvasive laboratory tests until the VSD has closed spontaneously. Echocardiography is used to estimate pulmonary artery pressure, screen for the development of left ventricular outflow tract pathology (subaortic membrane or aortic regurgitation), and to confirm spontaneous closure.

In infants with a large VSD, management has 2 aims: to get the symptoms of heart failure under control (see Chapter 442) and prevent the development of pulmonary vascular disease. If early treatment is successful, sometimes the shunt may diminish in size with spontaneous improvement, especially during the 1st yr of life. The clinician must be alert not to confuse clinical improvement caused by a decrease in defect size with clinical changes caused by the development of Eisenmenger physiology. Because catheter or surgical closure can be carried out at low risk in most infants, medical management should not be pursued in symptomatic infants after an initial unsuccessful trial. Because pulmonary vascular disease can usually be prevented when surgery is performed within the 1st yr of life, even infants with well-controlled heart failure should not have surgery delayed inordinately unless there is evidence that the defect is becoming pressure restrictive.

Indications for surgical closure of a VSD include patients at any age with large defects in whom clinical symptoms and failure to thrive cannot be controlled medically; infants between 6 and 12 mo of age with large defects associated with pulmonary hypertension, even if the symptoms are controlled by medication; and patients older than 24 mo with a Qp : Qs ratio greater than 2 : 1. Patients with a supracristal VSD of any size are usually referred for surgery because of the high risk for aortic valve regurgitation (see Chapter 426.7). Severe pulmonary vascular disease nonresponsive to pulmonary vasodilators is a contraindication to closure of a VSD.

Transcatheter occlusion closure is most successful in treating muscular VSDs, which may be difficult to access by surgery. Perimembranous VSD catheter closure has a high risk of postprocedure heart block and is not recommended. Hybrid methods employing a sternotomy with device placement through the anterior wall of the right ventricle under transesophageal echo and fluoroscopic visualization has been performed in difficult to approach muscular defects.

PROGNOSIS

The results of primary surgical repair are excellent, and complications leading to long-term problems (residual ventricular shunts requiring reoperation or heart block requiring a pacemaker) are rare. Pulmonary arterial palliative banding with repair in later childhood, once the standard of care, is now reserved for extremely complicated cases or very premature infants. Surgical risks are somewhat higher for defects in the muscular septum, particularly apical defects and multiple (Swiss cheese–type) VSDs. These patients may require pulmonary arterial banding if symptomatic, with subsequent debanding and repair of multiple VSDs at an older age.

After surgical obliteration of the left-to-right shunt, the hyperdynamic heart becomes quiet, cardiac size decreases toward normal (see Fig. 426-8), thrills and murmurs are abolished, and pulmonary artery hypertension regresses. The patient's clinical status improves markedly. Most infants begin to thrive, and cardiac medications are no longer required. Catch-up growth occurs in most patients within the next 1-2 yr. In some instances after successful surgery, systolic ejection murmurs of low intensity persist for months. The long-term prognosis after surgery is excellent. Patients with a small VSD and those who have undergone surgical closure without residua are considered to be at standard risk for health and life insurance.

426.7 Supracristal Ventricular Septal Defect with Aortic Insufficiency

Daniel Bernstein

A supracristal VSD is complicated by prolapse of the aortic valve into the defect and aortic insufficiency, which may eventually develop in 50-90% of these patients. Although supracristal VSD accounts for ≈5% of all patients with VSD, the incidence is higher in Asian children and in males. The VSD, which may be small or moderate in size, is located anterior to and directly below the pulmonary valve in the outlet septum, superior to the muscular ridge known as the *crista supraventricularis,* which separates the trabecular body of the right ventricle from the smooth outflow portion. The right or, less often, the noncoronary aortic cusp prolapses into the defect and may partially or even completely occlude it. Such occlusion may limit the amount of left-to-right shunting and give the false impression that the defect is not large.

Aortic insufficiency is most often not recognized until 5-9 yr life or beyond. Of note, aortic insufficiency is occasionally associated with VSDs located in the membranous septum.

Early heart failure secondary to a large left-to-right shunt rarely occurs, but without surgery, severe aortic insufficiency and left ventricular failure may ensue. The murmur of a supracristal VSD is usually heard at the mid to upper left sternal border, as opposed to the lower left sternal border, and it is sometimes confused with that of pulmonic stenosis. A decrescendo diastolic murmur will be appreciated at the upper right or mid left sternal borders if there is aortic insufficiency. More advanced degrees of aortic insufficiency will be associated with a wide pulse pressure and a hyperdynamic precordium. These clinical findings must be distinguished from PDA or other defects associated with aortic runoff.

The clinical manifestations vary widely from trivial aortic regurgitation and small left-to-right shunts in asymptomatic children to florid aortic insufficiency and massive cardiomegaly in symptomatic adolescents. Closure of all supracristal ventricular VSDs at the time of diagnosis is commonly recommended to prevent the development of aortic regurgitation, even in an asymptomatic child. Patients who already have significant aortic insufficiency require surgical intervention to prevent irreversible left ventricular dysfunction. Surgical options depend on the degree of damage to the valve. If the insufficiency is mild, they may include simple closure of the defect to bolster the valve apparatus without touching the valve itself, valvuloplasty for more significant degrees of involvement, and replacement with a prosthesis or homograft or aortopulmonary translocation for severe involvement.

426.8 Patent Ductus Arteriosus

Daniel Bernstein

During fetal life, most of the pulmonary arterial blood is shunted right-to-left through the ductus arteriosus into the aorta (see Chapter 421). Functional closure of the ductus normally occurs soon after birth, but if the ductus remains patent when pulmonary vascular resistance falls, aortic blood then is shunted left-to-right into the pulmonary artery. The aortic end of the ductus is just distal to the origin of the left subclavian artery, and the ductus enters the pulmonary artery at its bifurcation. Female patients with PDA outnumber males 2 : 1. PDA is also associated with maternal rubella infection during early pregnancy, an uncommon occurrence. PDA is a common problem in premature infants, as the smooth muscle in the wall of the preterm ductus is less responsive to high Po_2 and therefore less likely to constrict after birth. In these infants, it can cause severe hemodynamic derangements and several major sequelae (see Chapter 101.3).

When a term infant is found to have a PDA, the wall of the ductus is deficient in both the mucoid endothelial layer and the muscular media, whereas in the premature infant, the PDA usually has a normal structure. Thus, a PDA persisting beyond the 1st few wk of life in a term infant rarely closes spontaneously or with pharmacologic intervention, whereas if early pharmacologic or surgical intervention is not required in a premature infant, spontaneous closure occurs in most instances. A PDA is seen in 10% of patients with other congenital heart lesions and often plays a critical role in providing a source of pulmonary blood flow when the right ventricular outflow tract is stenotic or atretic (see Chapter 430) or in providing systemic blood flow in the presence of aortic coarctation or interruption (see Chapters 426.6 to 427.8).

PATHOPHYSIOLOGY

As a result of the higher aortic pressure postnatally, blood shunts left to right through the ductus, from the aorta to the pulmonary artery. The extent of the shunt depends on the size of the ductus and on the ratio of pulmonary to systemic vascular resistance. If the PDA is small, pressures within the pulmonary artery, the right ventricle, and the right atrium are normal. If the PDA is large, pulmonary artery pressure may be elevated to systemic levels during both systole and diastole. Thus, patients with a large PDA are at high risk for the development of pulmonary vascular disease if left unoperated.

CLINICAL MANIFESTATIONS

A small PDA is usually asymptomatic. A large PDA will result in heart failure similar to that encountered in infants with a large VSD. Retardation of physical growth may be a major manifestation in infants with large shunts. A small PDA is associated with normal peripheral pulses, and a large PDA results in bounding peripheral arterial pulses and a wide pulse pressure, due to runoff of blood into the pulmonary artery during diastole. The heart is normal in size when the ductus is small, but moderately or grossly enlarged in cases with a large communication. In these cases, the apical impulse is prominent and, with cardiac enlargement, is heaving. A thrill, maximal in the 2nd left interspace, is often present and may radiate toward the left clavicle, down the left sternal border, or toward the apex. It is usually systolic but may also be palpated throughout the cardiac cycle. The classic continuous murmur is described as being like machinery in quality. It begins soon after onset of the 1st sound, reaches maximal intensity at the end of systole, and wanes in late diastole. It may be localized to the 2nd left intercostal space or radiate down the left sternal border or to the left clavicle. When pulmonary vascular resistance is increased, the diastolic component of the murmur may be less prominent or absent. In patients with a large left-to-right shunt, a low-pitched mitral mid-diastolic murmur may be audible at the apex as a result of the increased volume of blood flow across the mitral valve.

DIAGNOSIS

If the left-to-right shunt is small, the electrocardiogram is normal; if the ductus is large, left ventricular or biventricular hypertrophy is present. The diagnosis of an isolated, uncomplicated PDA is untenable when right ventricular hypertrophy is present.

Radiographic studies in patients with a large PDA show a prominent pulmonary artery with increased pulmonary vascular markings. Cardiac size depends on the degree of left-to-right shunting; it may be normal or moderately to markedly enlarged. The chambers involved are the left atrium and left ventricle. The aortic knob may be normal or prominent.

On echocardiogram, the cardiac chambers will be normal in size if the ductus is small. With large shunts, left atrial and left ventricular dimensions are increased. The ductus can easily be visualized directly and its size estimated. Color and pulsed Doppler examinations demonstrate systolic or diastolic (or both) retrograde turbulent flow in the pulmonary artery, and aortic retrograde flow in diastole (Fig. 426-10) in the presence of a large shunt.

The clinical signs and echocardiographic findings are sufficiently distinctive to allow an accurate diagnosis by noninvasive methods in most patients. In rare patients with atypical findings, cardiac catheterization may be indicated for confirmation of diagnosis. Cardiac catheterization will demonstrate either normal or increased pressure in the right ventricle and pulmonary artery, depending on the size of the ductus. The presence of oxygenated blood shunting into the pulmonary artery confirms the left-to-right shunt. The catheter may pass from the pulmonary artery through the ductus into the descending aorta. Injection of contrast medium into the ascending aorta shows opacification of the pulmonary artery from the aorta and identifies the ductus.

Other conditions can produce systolic and diastolic murmurs in the pulmonic area in an acyanotic patient and are described in Chapter 422. An **aorticopulmonary window** defect may rarely be clinically indistinguishable from a patent ductus, although, in most cases, the murmur is only systolic and is loudest at the right rather than the left upper sternal border. A sinus of Valsalva aneurysm that has ruptured into the right side of the heart or pulmonary artery, coronary arteriovenous fistulas, and an aberrant left coronary artery with massive collaterals from the right coronary display dynamics similar to that of a PDA with a continuous murmur and a wide pulse pressure. Truncus arteriosus with torrential pulmonary flow also has an aortic runoff physiology. A peripheral arteriovenous fistula also results in a wide pulse pressure, but the distinctive precordial murmur of a PDA is not

present. VSD with aortic insufficiency, repaired tetralogy of Fallot, and combined aortic and mitral insufficiency (usually due to rheumatic fever) may be confused with a PDA, but the murmurs should be differentiated by their to-and-fro rather than continuous nature. The combination of a large VSD and a PDA results in findings more like those of an isolated VSD. Echocardiography should be able to eliminate these other diagnostic possibilities.

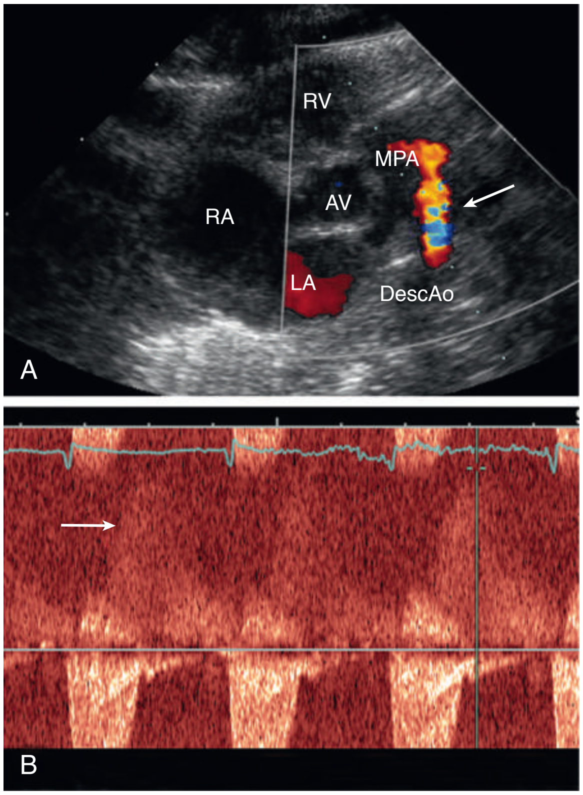

Figure 426-10 **Echocardiogram in a newborn with a small- to moderate-size patent ductus arteriosus. A,** Color Doppler performed in a parasternal short axis view shows flow *(arrow)* from the aorta into the main pulmonary artery. **B,** Doppler evaluation demonstrates retrograde diastolic flow into the pulmonary artery. AV, aortic valve; DescAo, descending aorta; LA, left atrium; MPA, main pulmonary artery; RA, right atrium; RV, right ventricle.

PROGNOSIS AND COMPLICATIONS

Spontaneous closure of the ductus after infancy is extremely rare. Patients with a small PDA may live a normal span with few or no cardiac symptoms, but late manifestations may occur. In patients with a large PDA, cardiac failure most often occurs in early infancy but may occur later in life, even with a moderate-sized communication.

Infective endarteritis may be seen at any age. Pulmonary or systemic emboli may occur. Rare complications include aneurysmal dilation of the pulmonary artery or the ductus, calcification of the ductus, noninfective thrombosis of the ductus with embolization, and paradoxical emboli. Pulmonary hypertension (Eisenmenger syndrome) usually develops in patients with a large PDA who do not undergo ductal closure (see Chapter 433.2).

TREATMENT

Irrespective of age, patients with PDA require catheter or surgical closure. In patients with a small PDA, the rationale for closure is prevention of bacterial endarteritis or other late complications. In patients with a moderate to large PDA, closure is accomplished to treat heart failure or prevent the development of pulmonary vascular disease, or both. Once the diagnosis of a moderate to large PDA is made, treatment should not be unduly postponed after adequate medical therapy for cardiac failure has been instituted.

Transcatheter PDA closure is routinely performed in the cardiac catheterization laboratory (Fig. 426-11). Small PDAs are generally closed with intravascular coils. Moderate to large PDAs may be closed with an umbrella-like device or with a catheter-introduced sac into which several coils are released. Surgical closure of a PDA can be accomplished by a standard left thoracotomy or using thoracoscopic minimally invasive techniques. Because the case fatality rate with interventional or surgical treatment is considerably less than 1% and the risk without it is greater, closure of the ductus is indicated in asymptomatic patients, preferably before 1 yr of age. Pulmonary hypertension is not a contraindication to surgery at any age if it can be demonstrated at cardiac catheterization that the shunt flow is still predominantly left to right and that severe pulmonary vascular disease is not present. After closure, symptoms of cardiac failure rapidly disappear. Infants who had failed to thrive usually have immediate improvement in physical development. The pulse and blood pressure return to normal, and the machinery-like murmur disappears. A functional systolic murmur over the pulmonary area may persist; it may represent turbulence in a persistently dilated pulmonary artery. The radiographic signs of cardiac enlargement and pulmonary overcirculation disappear over a period of several months, and the electrocardiogram becomes normal.

DescAo, descending aorta; LSCA, left subclavian artery.

PATENT DUCTUS ARTERIOSUS IN LOW BIRTHWEIGHT INFANTS

See Chapter 101.

Bibliography is available at Expert Consult.

426.9 Aortopulmonary Window Defect

Daniel Bernstein

An aortopulmonary window defect consists of a communication between the ascending aorta and the main pulmonary artery. The presence of pulmonary and aortic valves and an intact ventricular septum distinguishes this anomaly from truncus arteriosus (see Chapter 431.8). Symptoms of heart failure appear during early infancy; occasionally, minimal cyanosis is present. The defect is usually large, and the cardiac murmur is usually systolic with an apical mid-diastolic rumble as a result of the increased blood flow across the mitral valve. In the rare instance when the communication is smaller and pulmonary hypertension is absent, the findings on examination can mimic those of a PDA (wide pulse pressure and a continuous murmur at the upper sternal borders). The electrocardiogram shows either left ventricular or biventricular hypertrophy. Radiographic studies demonstrate cardiac enlargement and prominence of the pulmonary artery and intrapulmonary vasculature. The echocardiogram shows enlarged left-sided heart chambers; the window defect can best be delineated with color flow Doppler. CT or MRI angiography can also be used to visualize the defect (see Fig. 423-26 in Chapter 423).

Cardiac catheterization, usually performed in older children to evaluate pulmonary vascular resistance, reveals a left-to-right shunt at the level of the pulmonary artery, as well as hyperkinetic pulmonary hypertension, because the defect is almost always large. Selective aortography with injection of contrast medium into the ascending aorta demonstrates the lesion, and manipulation of the catheter from the main pulmonary artery directly to the ascending aorta is also diagnostic.

An aortopulmonary window defect is surgically corrected during infancy. If surgery is not carried out in infancy, survivors carry the risk of progressive pulmonary vascular obstructive disease, similar to that of other patients who have large intracardiac or great vessel communications.

426.10 Coronary Artery Fistula

Daniel Bernstein

A congenital fistula may exist between a coronary artery and an atrium, ventricle (especially the right), or pulmonary artery. Sometimes, multiple fistulas exist. Regardless of the recipient chamber, the clinical signs are similar to those of PDA, although the machinery-like murmur may be more diffuse. If the flow is substantial, the involved coronary artery may be dilated or aneurysmal. The anatomic abnormality is usually demonstrable by color flow Doppler echocardiography and, during catheterization, by injection of contrast medium into the ascending aorta. Small fistulas may be hemodynamically insignificant and may even close spontaneously. If the shunt is large, treatment consists of either transcatheter coil embolization or, for lesions not amenable to catheter intervention, surgical closure of the fistula.

426.11 Ruptured Sinus of Valsalva Aneurysm

Daniel Bernstein

When 1 of the sinuses of Valsalva of the aorta is weakened by congenital or acquired disease, an aneurysm may form and eventually rupture, usually into the right atrium or ventricle. This condition is extremely rare in childhood. The onset is usually sudden. The diagnosis should be suspected in a patient in whom symptoms of acute heart failure develop in association with a new loud to-and-fro murmur. Color Doppler echocardiography and cardiac catheterization demonstrate the left-to-right shunt at the atrial or ventricular level. Urgent surgical repair is generally required. This condition is often associated with infective endocarditis of the aortic valve.

Chapter **427**

Acyanotic Congenital Heart Disease: Obstructive Lesions

427.1 Pulmonary Valve Stenosis with Intact Ventricular Septum

Daniel Bernstein

Of the various forms of right ventricular outflow obstruction with an intact ventricular septum, the most common is isolated valvular pulmonary stenosis, which accounts for 7-10% of all congenital heart defects. The valve cusps are deformed to various degrees and, as a result, the valve opens incompletely during systole. The valve may be bicuspid or tricuspid and the leaflets partially fused together with an eccentric outlet. This fusion may be so severe that only a pinhole central opening remains. If the valve is not severely thickened, it produces a dome-like obstruction to right ventricular outflow during systole. Isolated infundibular or subvalvular stenosis, supravalvular pulmonary stenosis, and branch pulmonary artery stenosis are also encountered. In cases where pulmonary valve stenosis is associated with a ventricular septal defect (VSD) but without anterior deviation of the infundibular septum and overriding aorta, this condition is better classified as pulmonary stenosis with VSD rather than as tetralogy of Fallot (see Chapter 430.1). Pulmonary stenosis and an atrial septal defect (ASD) are also occasionally seen as associated defects. The clinical and laboratory findings reflect the dominant lesion, but it is important to rule out any associated anomalies. Pulmonary stenosis as a result of valve dysplasia is the most common cardiac abnormality in **Noonan syndrome** (see Chapter 81), and is associated, in approximately 50% of cases, with a mutation in the gene *PTPN11,* encoding the protein tyrosine phosphatase SHP-2 on chromosome 12. The mechanism for pulmonic stenosis is unknown, although maldevelopment of the distal portion of the bulbus cordis and the sequelae of fetal endocarditis have been suggested as etiologies. Pulmonary stenosis can also be a component of **LEOPARD syndrome** (lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, deafness syndrome), often associated with hypertrophic cardiomyopathy. Mutations in the genes PTPN11, RAF1 and BRAF have been implicated in LEOPARD syndrome. Pulmonary stenosis, either of the valve or the branch pulmonary arteries, is a common finding in patients with arteriohepatic dysplasia, also known as **Alagille syndrome** (see Chapter 356). In this syndrome and in some patients with isolated pulmonic stenosis, a mutation is present in the *Jagged1* gene.

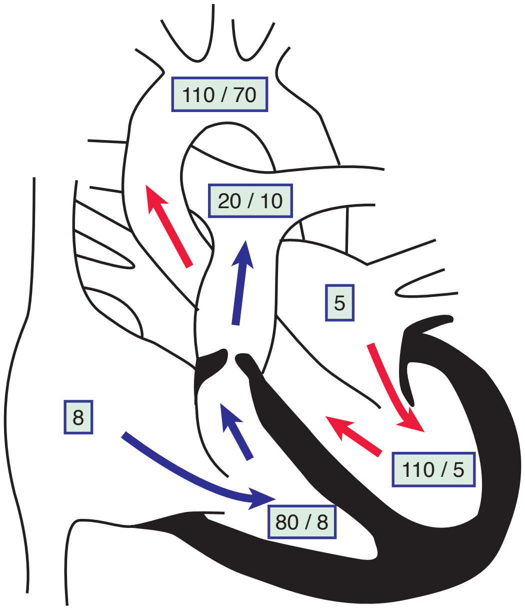

Figure 427-1 Physiology of valvular pulmonary stenosis. Boxed numbers represent pressure in mm Hg. Because of the absence of right-to-left or left-to-right shunting, blood flow through all cardiac chambers is normal at 3 L/min/m^2. The pulmonary-to-systemic blood flow ratio (Qp : Qs) is 1 : 1. Right atrial pressure is increased slightly as a result of decreased right ventricular compliance. The right ventricle is hypertrophied, and systolic and diastolic pressure is increased. The pressure gradient across the thickened pulmonary valve is 60 mm Hg. The main pulmonary artery pressure is slightly low, and poststenotic dilation is present. Left-heart pressure is normal. Unless right-to-left shunting is occurring through a foramen ovale, the patient's systemic oxygen saturation will be normal.

PATHOPHYSIOLOGY

The obstruction to outflow from the right ventricle to the pulmonary artery results in increased right ventricular systolic pressure and wall stress, which leads to hypertrophy of the right ventricle (Fig. 427-1). The severity of these abnormalities depends on the size of the restricted valve opening. In severe cases, right ventricular pressure may be higher than systemic arterial systolic pressure, whereas with milder obstruction, right ventricular pressure is only mildly or moderately elevated. Pulmonary artery pressure (distal to the obstruction) is normal or decreased. Arterial oxygen saturation will be normal even in cases of severe stenosis, unless an intracardiac communication such as a VSD or ASD is allowing blood to shunt from right to left. When severe pulmonic stenosis occurs in a neonate, decreased right ventricular compliance often leads to cyanosis as a result of right-to-left shunting through a patent foramen ovale, a condition termed ***critical pulmonic stenosis***.

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

Patients with mild or moderate stenosis usually do not have any symptoms. Growth and development are most often normal. If the stenosis is severe, signs of right ventricular failure such as hepatomegaly, peripheral edema, and exercise intolerance may be present. In a neonate or young infant with critical pulmonic stenosis, signs of right ventricular failure may be more prominent, and cyanosis is often present because of right-to-left shunting at the foramen ovale.

With **mild pulmonary stenosis,** venous pressure and pulse are normal. The heart is not enlarged, the apical impulse is normal, and the right ventricular impulse is not palpable. A sharp pulmonic ejection click immediately after the 1st heart sound is heard at the left upper sternal border during expiration. The 2nd heart sound is split, with a pulmonary component of normal intensity that may be slightly delayed. A relatively short, low- or medium-pitched systolic ejection murmur is maximally audible over the pulmonic area and radiates minimally to the lung fields bilaterally. The electrocardiogram is normal or characteristic of mild right ventricular hypertrophy; inversion of the T waves in the right precordial leads may be seen. Remember that the T wave in lead V_1 should normally be inverted until at least 6-8 yr of age. Therefore, a positive T wave in V_1 in a young child is a sign of right ventricular hypertrophy. The only abnormality demonstrable radiographically is usually poststenotic dilation of the pulmonary artery. Two-dimensional echocardiography shows right ventricular hypertrophy and a slightly thickened pulmonic valve, which domes in systole; Doppler studies demonstrate a right ventricle to pulmonary artery gradient of ≤30 mm Hg.

In **moderate pulmonic stenosis,** venous pressure may be slightly elevated; in older children, a prominent *a* wave may be noted in the jugular pulse. A right ventricular lift may be palpable at the lower left sternal border. The 2nd heart sound is split, with a delayed and soft pulmonary component. As valve motion becomes more limited with more severe degrees of stenosis, both the pulmonic ejection click and the pulmonic 2nd sound may become inaudible. With increasing degrees of stenosis, the peak of the systolic ejection murmur is prolonged later into systole, and its quality becomes louder and harsher (higher frequency). The murmur radiates more prominently to both lung fields.

The electrocardiogram reveals right ventricular hypertrophy, sometimes with a prominent spiked P wave. Radiographically, the heart can vary from normal size to mildly enlarged with uptilting of the apex because of the prominence of the right ventricle; pulmonary vascularity may be normal or slightly decreased. The echocardiogram shows a thickened pulmonic valve with restricted systolic motion. Doppler examination demonstrates a right ventricle to pulmonary artery pressure gradient in the 30-60 mm Hg range. Mild tricuspid regurgitation may be present and allows Doppler confirmation of right ventricular systolic pressure.

In **severe stenosis,** mild to moderate cyanosis may be noted in patients with an interatrial communication (ASD or patent foramen ovale). In the absence of any intracardiac shunt, cyanosis is absent. If hepatic enlargement and peripheral edema are present, they are an indication of right ventricular failure. Elevation of venous pressure is common and is caused by a large presystolic jugular *a* wave. The heart is moderately or greatly enlarged, and a conspicuous parasternal right ventricular lift is present and frequently extends to the left midclavicular line. The pulmonary component of the 2nd sound is usually inaudible. A loud, long, and harsh systolic ejection murmur, usually accompanied by a thrill, is maximally audible in the pulmonic area and may radiate over the entire precordium, to both lung fields, into the neck, and to the back. The peak of the murmur occurs later in systole as valve opening becomes more restricted. The murmur frequently encompasses the aortic component of the 2nd sound but is not preceded by an ejection click.

The electrocardiogram shows gross right ventricular hypertrophy, frequently accompanied by a tall, spiked P wave. Radiographic studies confirm the presence of cardiac enlargement with prominence of the right ventricle and right atrium. Prominence of the main pulmonary artery segment may be seen due to poststenotic dilation (Fig. 427-2). Intrapulmonary vascularity is decreased. The 2-dimensional echocardiogram shows severe deformity of the pulmonary valve and right ventricular hypertrophy (Fig. 427-3). In the late stages of the disease, systolic dysfunction of the right ventricle may be seen, and in these cases the ventricle may become dilated, with prominent tricuspid regurgitation. Doppler studies demonstrate a high gradient (>60 mm Hg) across the pulmonary valve. The classic findings of severe pulmonary stenosis in older children are rarely seen because of early intervention. Signs of critical pulmonic stenosis, with all of the features of severe pulmonic stenosis plus cyanosis, are usually encountered in the neonatal period.

Cardiac catheterization is not generally required for diagnostic purposes but is undertaken as part of a **balloon valvuloplasty** procedure. Catheterization demonstrates an abrupt pressure gradient across the

Figure 427-2 **X-ray of a patient with valvular pulmonary stenosis and a normal aortic root.** The heart size is within normal limits, but post-stenotic dilation of the pulmonary artery is present.

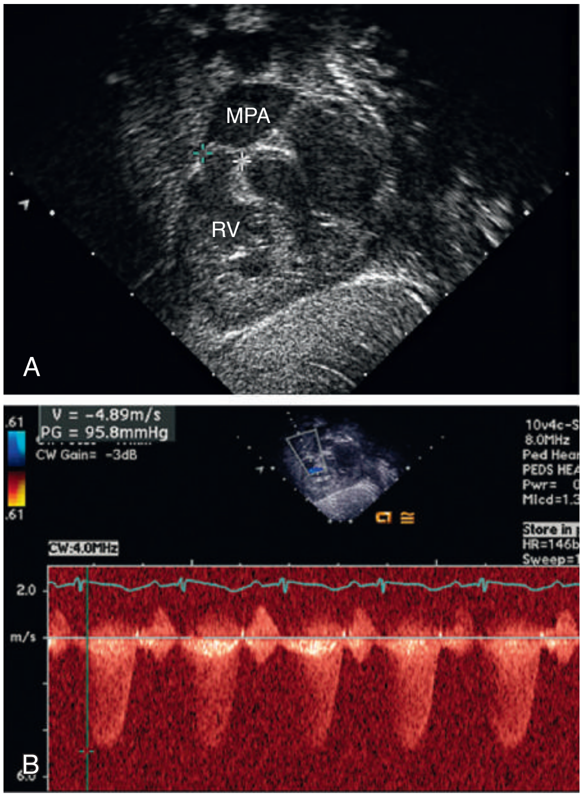

Figure 427-3 **Echocardiogram demonstrating valvar pulmonic stenosis. A,** Subcostal view showing thickened pulmonary valve leaflets (between crosshatches). **B,** Doppler study indicating a 95 mm Hg peak pressure gradient across the stenotic valve. MPA, main pulmonary artery; RV, right ventricle.

pulmonary valve. Pulmonary artery pressure is either normal or low. The severity of the stenosis is graded based on the ratio of right ventricular systolic pressure to systemic systolic pressure or the right ventricle to pulmonary artery pressure gradient: a gradient of 10-30 mm Hg in mild cases, 30-60 mm Hg in moderate cases, and >60 mm Hg or with right ventricular pressure greater than systemic pressure in severe cases. If cardiac output is low or a significant right-to-left shunt exists across the atrial septum, the pressure gradient may underestimate the degree of valve stenosis. Selective right ventriculography demonstrates the thickened, poorly mobile valve. In mild to moderate stenosis, doming of the valve in systole is readily seen. Flow of contrast medium through the stenotic valve in ventricular systole produces a narrow jet of dye that fills the dilated main pulmonary artery. Subvalvular hypertrophy that may intensify the obstruction may be present.

TREATMENT

Patients with moderate or severe isolated pulmonary stenosis require relief of the obstruction. Balloon valvuloplasty is the initial treatment of choice for the majority of patients (Fig. 427-4). Patients with severely thickened pulmonic valves, especially common in those with Noonan syndrome, may require surgical intervention. In a neonate with critical pulmonic stenosis, urgent treatment by either balloon valvuloplasty or surgical valvotomy is warranted.

Excellent results are obtained in most instances. The gradient across the pulmonary valve is markedly reduced or abolished. In the early period after balloon valvuloplasty, a small to moderate residual gradient may remain because of muscular infundibular narrowing; it usually resolves with time. A short, early decrescendo diastolic murmur may be heard at the mid to upper left sternal border as a result of pulmonary valvular insufficiency. The degree of insufficiency is not usually clinically significant. No difference in patient status after valvuloplasty or surgery is noted at late follow-up; recurrence is unusual after successful treatment except in those patients with extremely dysplastic valves. In the small minority of patients where the degree of pulmonary regurgitation is more severe, right ventricular dilation may ensue, and these patients require careful follow-up and may require surgical intervention.

PROGNOSIS AND COMPLICATIONS

Heart failure occurs only in severe cases and most often during the 1st mo of life. The development of cyanosis from a right-to-left shunt across a foramen ovale is almost exclusively seen in the neonatal period when the stenosis is severe. Infective endocarditis is a risk, but is not common in childhood.

Children with mild stenosis can lead a normal life, but their progress should be evaluated at regular intervals. Patients who have small gradients rarely show progression and do not need intervention, but a significant gradient is more likely to develop in children with moderate stenosis as they grow older. Worsening of obstruction may also be due to the development of secondary subvalvular muscular and fibrous tissue hypertrophy. In untreated severe stenosis, the course may abruptly worsen with the development of right ventricular dysfunction and cardiac failure. Infants with critical pulmonic stenosis require urgent catheter balloon valvuloplasty or surgical valvotomy. Development of right ventricular failure many years after pulmonary balloon valvuloplasty is uncommon. Nonetheless, patients should be followed serially for worsening pulmonary insufficiency and right ventricular dilation.

Bibliography is available at Expert Consult.

427.2 Infundibular Pulmonary Stenosis and Double-Chamber Right Ventricle

Daniel Bernstein

Infundibular pulmonary stenosis is caused by muscular or fibrous obstruction in the outflow tract of the right ventricle. The site of obstruction may be close to the pulmonary valve or well below it; an infundibular chamber may be present between the right ventricular cavity and the pulmonary valve. In many cases, a VSD may have been present initially and later closed spontaneously. When the pulmonary valve is also stenotic, the combined defect is primarily classified as valvular stenosis with secondary infundibular hypertrophy. The hemodynamics and clinical manifestations of patients with isolated infundibular pulmonary stenosis are similar, for the most part, to those described in the discussion of isolated valvular pulmonary stenosis (see Chapter 427.1).

A common variation in right ventricular outflow obstruction below the pulmonary valve is that of a double-chambered right ventricle. In this condition, a muscular band is present in the mid-right ventricular region; the band divides the chamber into 2 parts and creates obstruction between the inlet and outlet portions. An associated VSD that may close spontaneously is often noted. Obstruction is not usually seen early in life but may progress rapidly in a similar manner to the progressive infundibular obstruction observed with tetralogy of Fallot (see Chapter 430.1).

The diagnosis of isolated right ventricular infundibular stenosis or double-chambered right ventricle is usually made by echocardiography. The ventricular septum must be evaluated carefully to determine whether an associated VSD is present. The prognosis for untreated cases of severe right ventricular outflow obstruction is similar to that for valvular pulmonary stenosis. When the obstruction is moderate to severe, surgery is indicated. After surgery, the pressure gradient is abolished or markedly reduced and the long-term outlook is excellent.

427.3 Pulmonary Stenosis in Combination with an Intracardiac Shunt

Daniel Bernstein

Valvular or infundibular pulmonary stenosis, or both, may be associated with either an ASD or a VSD. In these patients, the clinical features depend on the degree of pulmonary stenosis, which determines whether the net shunt is from left to right or from right to left.

The presence of a large left-to-right shunt at the atrial or ventricular level is evidence that the pulmonary stenosis is mild. These patients have symptoms similar to those of patients with an isolated ASD or VSD. With increasing age, worsening of the obstruction may limit the shunt and result in a gradual improvement in symptoms. Eventually, particularly in patients with pulmonary stenosis and VSD, a further increase in obstruction may lead to right-to-left shunting and cyanosis. When a patient with a VSD has evidence of decreasing heart failure and increased right ventricular forces on the electrocardiogram, one must differentiate between the development of increasing pulmonary stenosis versus the onset of pulmonary vascular disease (Eisenmenger syndrome, Chapter 433.2).

These anomalies are readily repaired surgically. Defects in the atrial or ventricular septum are closed, and the pulmonary stenosis is relieved by resection of infundibular muscle or pulmonary valvotomy, or both, as indicated. Patients with a predominant right-to-left shunt have symptoms similar to those of patients with **tetralogy of Fallot** (see Chapter 430.1).

427.4 Peripheral Pulmonary Stenosis

Daniel Bernstein

Single or multiple constrictions may occur anywhere along the major branches of the pulmonary arteries and may range from mild to severe and from localized to extensive. Frequently, these defects are associated with other types of congenital heart disease, including valvular pulmonic stenosis, tetralogy of Fallot, patent ductus arteriosus (PDA), VSD, ASD, and supravalvular aortic stenosis. A familial tendency has been recognized in some patients with peripheral pulmonic stenosis. A high incidence is found in infants with congenital rubella syndrome. The combination of supravalvular aortic stenosis with pulmonary arterial branch stenosis, idiopathic hypercalcemia of infancy, elfin facies, and mental retardation is known as **Williams syndrome,** a condition associated with deletion of the elastin gene in region 7q11.23 on chromosome 7. Peripheral pulmonary stenosis is also associated with the **Alagille syndrome,** which may be associated with a mutation in the *Jagged1* gene.

A mild constriction has little effect on the pulmonary circulation. With multiple severe constrictions, pressure is increased in the right ventricle and in the pulmonary artery proximal to the site of obstruction. When the anomaly is isolated, the diagnosis is suspected by the presence of murmurs in widespread locations over the chest, either anteriorly or posteriorly. These murmurs are usually systolic ejection in quality but may be continuous. Most often, the physical signs are dominated by the associated anomaly, such as tetralogy of Fallot (see Chapter 430.1).

In the immediate newborn period, a mild and transient form of peripheral pulmonic stenosis may be present. Physical findings are generally limited to a soft systolic ejection murmur, which can be heard over either or both lung fields. It is the absence of other physical findings of valvular pulmonic stenosis (right ventricular lift, soft pulmonic 2nd sound, systolic ejection click, murmur loudest at the upper left sternal border) that supports this diagnosis. This murmur usually disappears by 1-2 mo.

If the stenosis is severe, the electrocardiogram shows evidence of right ventricular and right atrial hypertrophy, and the chest radiograph shows cardiomegaly and prominence of the main pulmonary artery. The pulmonary vasculature is usually normal; in some cases, however, small intrapulmonary vascular shadows are seen that represent areas of poststenotic dilation. Echocardiography is limited in its ability to visualize the distal branch pulmonary arteries. Doppler examination demonstrates the acceleration of blood flow through the stenoses and, if tricuspid regurgitation is present, allows an estimation of right ventricular systolic pressure. MRI and CT are extremely helpful in delineating distal obstructions; if moderate to severe disease is suspected, the diagnosis is usually confirmed by cardiac catheterization.

Severe obstruction of the main pulmonary artery and its primary branches can be relieved during corrective surgery for associated lesions such as the tetralogy of Fallot or valvular pulmonary stenosis. If peripheral pulmonic stenosis is isolated, it may be treated by catheter balloon dilation, sometimes with placement of an intravascular stent (see Fig. 423-29 in Chapter 423).

427.5 Aortic Stenosis

Daniel Bernstein

PATHOPHYSIOLOGY

Congenital aortic stenosis accounts for ≈5% of cardiac malformations recognized in childhood; a bicuspid aortic valve, one of the most common congenital heart lesions overall, is identified in up to 1.5% of adults and may be asymptomatic in childhood. Aortic stenosis is more frequent in males (3:1). There are families with multiple individuals affected with bicuspid aortic valve, and several genes have been implicated, including *NOTCH1* on chromosome 9q34.3.

In the most common form, valvular aortic stenosis, the leaflets are thickened and the commissures are fused to varying degrees. Left ventricular systolic pressure is increased as a result of the obstruction to outflow. The left ventricular wall hypertrophies in compensation; as its compliance decreases, end-diastolic pressure increases as well.

Subvalvular (subaortic) stenosis with a discrete fibromuscular shelf below the aortic valve is also an important form of left ventricular outflow tract obstruction. This lesion is frequently associated with other forms of congenital heart disease such as mitral stenosis and coarctation of the aorta (**Shone syndrome**) and may progress rapidly in severity. It is less commonly diagnosed during early infancy and may develop despite previous documentation of no left ventricular outflow tract obstruction. Subvalvular aortic stenosis may become apparent after successful surgery for other congenital heart defects (coarctation of the aorta, PDA, VSD), may develop in association with mild lesions that have not been surgically repaired, or may occur as an isolated abnormality. Subvalvular aortic stenosis may also be caused by a markedly hypertrophied ventricular septum in association with hypertrophic cardiomyopathy (see Chapter 439.2).

Supravalvular aortic stenosis, the least-common type, may be sporadic, familial, or associated with **Williams syndrome,** which includes mental retardation (IQ range: 41-80), elfin facies (full face, broad forehead, flattened bridge of the nose, long upper lip, and rounded cheeks) (Fig. 427-5), and idiopathic hypercalcemia of infancy. Additional features include loquacious personality, hypersensitivity to sound, spasticity, hypoplastic nails, dental anomalies (partial anodontia, microdontia enamel hypoplasia), joint hypermobility, nephrocalcinosis, hypothyroidism, and poor weight gain. Narrowing of the coronary artery ostia can occur in patients with supravalvar aortic stenosis and should be carefully evaluated. Stenosis of other arteries, in particular, the branch pulmonary arteries, may also be present. Williams syndrome has been shown to be due to a deletion involving the elastin gene on chromosome 7q11.23.

Figure 427-5 Williams syndrome. *(From Jones KL, Smith DW: The Williams elfin facies syndrome: a new perspective,* J Pediatr *86:718, 1975.)*

CLINICAL MANIFESTATIONS

Symptoms in patients with aortic stenosis depend on the severity of the obstruction. Severe aortic stenosis that occurs in early infancy is termed **critical aortic stenosis** and is associated with left ventricular failure and signs of low cardiac output. Heart failure, cardiomegaly, and pulmonary edema are severe, the pulses are weak in all extremities, and the skin may be pale or grayish. Urine output may be diminished. If cardiac output is significantly decreased, the intensity of the murmur at the right upper sternal border may be minimal. Most children with less-severe forms of aortic stenosis remain asymptomatic and display normal growth and development. The murmur is usually discovered during routine physical examination. Rarely, fatigue, angina, dizziness, or syncope may develop in an older child with previously undiagnosed severe obstruction to left ventricular outflow. Sudden death has been reported with aortic stenosis but usually occurs in patients with severe left ventricular outflow obstruction in whom surgical relief has been delayed.

The physical findings are dependent on the degree of obstruction to left ventricular outflow. In mild stenosis, the pulses, heart size, and apical impulse are all normal. With increasing degrees of severity, the pulses become diminished in intensity and the heart may be enlarged, with a left ventricular apical thrust. Mild to moderate valvular aortic stenosis is usually associated with an early systolic ejection click, best heard at the apex and left sternal edge. Unlike the click in pulmonic stenosis, its intensity does not vary with respiration. Clicks are unusual in more-severe aortic stenosis or in discrete subaortic stenosis. If the stenosis is severe, the 1st heart sound may be diminished because of decreased compliance of the thickened left ventricle. Normal splitting of the 2nd heart sound is present in mild to moderate obstruction. In patients with severe obstruction, the intensity of aortic valve closure is diminished, and, rarely in children, the 2nd sound may be split paradoxically (becoming wider in expiration). A 4th heart sound may be audible when the obstruction is severe as a result of decreased left ventricular compliance.

The intensity, pitch, and duration of the systolic ejection murmur are other indications of severity. The louder, harsher (higher pitch), and longer the murmur, the greater the degree of obstruction is. The typical murmur is audible maximally at the right upper sternal border and radiates to the neck and the left midsternal border. It is usually accompanied by a thrill in the suprasternal notch. In patients with subvalvular aortic stenosis, the murmur may be maximal along the left sternal border or even at the apex. A soft decrescendo diastolic murmur indicative of aortic insufficiency is often present when the obstruction is subvalvular or in patients with a bicuspid aortic valve. Occasionally, an apical short mid-diastolic rumbling murmur is audible; this murmur should raise suspicion of associated mitral valve stenosis.

LABORATORY FINDINGS AND DIAGNOSIS

The diagnosis can usually be made on the basis of the physical examination and the severity of obstruction confirmed by laboratory tests. If the pressure gradient across the aortic valve is mild, the electrocardiogram is likely to be normal. The electrocardiogram may occasionally be normal even with more severe obstruction, but evidence of left ventricular hypertrophy and strain (inverted T waves in the left precordial leads) is generally present if severe stenosis is long-standing. The chest radiograph frequently shows a prominent ascending aorta, but the aortic knob is normal. Heart size is typically normal. Valvular calcification has been noted only in older children and adults. Echocardiography identifies both the site and the severity of the obstruction. Two-dimensional imaging shows left ventricular hypertrophy and the thickened and domed aortic valve (Fig. 427-6). The echo will also demonstrate the number of valve leaflets and their morphology, and the presence of a subaortic membrane or supravalvar stenosis. Associated anomalies of the mitral valve or aortic arch or a VSD or PDA are present in up to 20% of cases. In the absence of left ventricular failure, the shortening fraction of the left ventricle may be increased because the ventricle is hypercontractile. In infants with critical aortic stenosis, the left ventricular shortening fraction is usually decreased and may be quite poor. The endocardium may appear bright, indicative of the development of endocardial fibrous scarring, known as **endocardial fibroelastosis.** Doppler studies show the specific site of obstruction and determine the peak and mean systolic left ventricular outflow tract gradients. When severe aortic obstruction is associated with left ventricular dysfunction, the Doppler-derived valve gradient may markedly underestimate the severity of the obstruction because of the low cardiac output across the valve.

Left-heart catheterization, usually performed in conjunction with aortic balloon valvuloplasty, demonstrates the magnitude of the pressure gradient from the left ventricle to the aorta. The aortic pressure curve is abnormal if the obstruction is severe. In patients with severe obstruction and decreased left ventricular compliance, left atrial pressure is increased and pulmonary hypertension may be present. When a critically ill infant with left ventricular outflow tract obstruction undergoes cardiac catheterization, left ventricular function is often markedly decreased. As with the echocardiogram, the gradient measured across the stenotic aortic valve may underestimate the degree of obstruction because of low cardiac output. Actual measurement of cardiac output by thermodilution and calculation of the aortic valve area may be helpful.

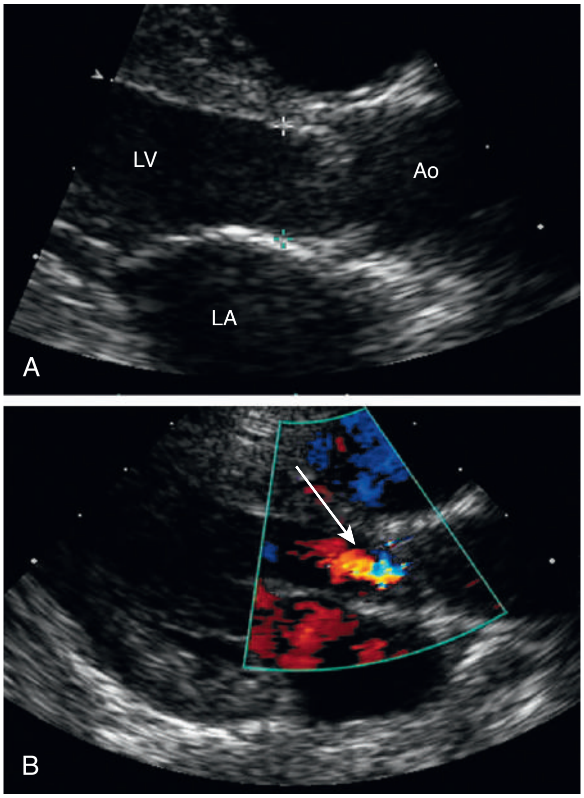

Figure 427-6 Echocardiogram showing valvar aortic stenosis with regurgitation. **A,** In this parasternal long axis view, the stenotic aortic valve can be seen doming in systole. The *crosshatch* marks delineate the aortic annulus. **B,** Doppler study shows the presence of aortic regurgitation *(arrow)*. Ao, aorta; LA, left atrium; LV, left ventricle.

TREATMENT

Balloon valvuloplasty is indicated for children with moderate to severe valvular aortic stenosis to prevent progressive left ventricular dysfunction and the risk of syncope and sudden death. Valvuloplasty should be advised when the peak-to-peak systolic gradient between the left ventricle and aorta exceeds 60-70 mm Hg at rest, assuming normal cardiac output, or for lesser gradients when symptoms or electrocardiographic changes are present. For more rapidly progressive subaortic obstructive lesions, a gradient of 40-50 mm Hg or the presence of aortic insufficiency is considered an indication for surgery. Balloon valvuloplasty is the procedure of choice even in the neonatal period. Surgical treatment is usually reserved for extremely dysplastic aortic valves that are not amenable to balloon therapy or in patients who also have subvalvar or valvar (also known as *supravalvar*) stenosis.

Discrete subaortic stenosis can be resected without damage to the aortic valve, the anterior leaflet of the mitral valve, or the conduction system. This type of obstruction is not usually amenable to catheter treatment. Relief of supravalvular stenosis is also achieved surgically, and the results are excellent if the area of obstruction is discrete and not associated with a hypoplastic aorta. In association with supravalvular aortic stenosis, one or both coronary arteries may be stenotic at their origins because of a thick supra-aortic fibrous ridge. For patients who have aortic stenosis in association with severe tunnel-like subaortic obstruction, the left ventricular outflow tract can be enlarged by “borrowing” space anteriorly from the right ventricular outflow tract (the Konno procedure).

Regardless of whether surgical or catheter treatment has been carried out, aortic insufficiency or calcification with re-stenosis is likely to occur years or even decades later and eventually require reoperation and often aortic valve replacement. When recurrence develops, it may not be associated with early symptoms. Signs of recurrent stenosis include electrocardiographic signs of left ventricular hypertrophy, an increase in the Doppler echocardiographic gradient, deterioration in echocardiographic indices of left ventricular function, and recurrence of signs or symptoms during graded treadmill exercise. Evidence of significant aortic regurgitation includes symptoms of heart failure, cardiac enlargement on roentgenogram, and left ventricular dilation on echocardiogram. The choice of reparative procedure depends on the relative degree of stenosis and regurgitation.

When **aortic valve replacement** is necessary, the choice of procedure often depends on the age of the patient. Homograft valves tend to calcify more rapidly in younger children, but they do not require chronic anticoagulation. Mechanical prosthetic valves are much longer lasting, yet they require anticoagulation, which can be difficult to manage in young children. In adolescent girls who are nearing childbearing age, consideration of the teratogenic effects of warfarin may warrant the use of a homograft valve. None of these options are perfect for a younger child who requires valve replacement because neither homograft nor mechanical valves grow with the patient. An alternative operation is **aortopulmonary translocation (Ross procedure);** it involves removing the patient’s own pulmonary valve and using it to replace the abnormal aortic valve. A homograft is then placed in the pulmonary position. The potential advantage of this procedure is the possibility for growth of the translocated living “neoaortic” valve and the increased longevity of the homograft valve when placed in the lower pressure pulmonary circulation. The long-term success of this operation, especially in young children, is still being investigated. Transcatheter stent valves, which are tissue valves sewn into the inside

of an expandable metal stent, are currently in clinical trials in adults, mainly in those who are not good candidates for standard surgical replacement. These can be implanted in the cardiac catheterization laboratory using a percutaneous approach. Tissue-engineered replacement valves grown in the laboratory from the patient's own arterial endothelial cells are another prospect for long-term palliation and are currently under development in animal models.

PROGNOSIS

Neonates with critical aortic stenosis may have severe heart failure and deteriorate rapidly to a low-output shock state. Emergency surgery or balloon valvuloplasty is lifesaving, but the mortality risk is not trivial. Neonates who die of critical aortic stenosis frequently have significant left ventricular endocardial fibroelastosis. Those who survive may develop signs of left ventricular diastolic muscle dysfunction (restrictive cardiomyopathy) and require cardiac transplantation (see Chapter 443).

In older infants and children with mild to moderate aortic stenosis, the prognosis is reasonably good, although disease progression over a period of 5-10 yr is common. Patients with aortic valve gradients <40-50 mm Hg are considered to have mild disease; those with gradients of 40-70 mm Hg have moderate disease. These patients usually respond well to treatment (either surgery or valvuloplasty), although reoperations on the aortic valve are often required later in childhood or in adult life, and many patients eventually require valve replacement. In unoperated patients with severe obstruction, sudden death is a significant risk and often occurs during or immediately after exercise. Aortic stenosis is one of the causes of sudden cardiac death in the pediatric age group.

Patients with moderate to severe degrees of aortic stenosis should not participate in active competitive sports. In those with milder disease, sports participation is less severely restricted. The status of each patient should be reviewed at least annually and intervention advised if progression of signs or symptoms occurs. Prophylaxis against infective endocarditis is no longer recommended unless a prosthetic valve has been inserted.

Older children and adults with isolated bicuspid aortic valve are at increased risk for developing dilation of their ascending aorta, even in the absence of significant stenosis. This risk increases with age, and the rate of increase is greatest in those with the largest aortic roots. In children, this dilation is usually mild and remains stable over many years of observation, but in older patients the aorta can dilate substantially and progressively. Whether these patients have some undiagnosed form of connective tissue disorder remains to be determined (as this form of dilation is similar to that seen in Marfan syndrome). Patients with Turner syndrome and bicuspid aortic valve do have an increased risk of aortic dilation. Although dissection and rupture are described complications of severe aortic root dilation in adults, there is not yet sufficient data to determine these risks in children. Only isolated cases have been reported.

Bibliography is available at Expert Consult.

427.6 Coarctation of the Aorta

Daniel Bernstein

Constrictions of the aorta of varying degrees may occur at any point from the transverse arch to the iliac bifurcation, but 98% occur just below the origin of the left subclavian artery at the origin of the ductus arteriosus (juxtaductal coarctation). The anomaly occurs twice as often in males as in females. Coarctation of the aorta may be a feature of **Turner syndrome** (see Chapters 81 and 586.1) and is associated with a bicuspid aortic valve in more than 70% of patients. Mitral valve abnormalities (a supravalvular mitral ring or parachute mitral valve) and subaortic stenosis are potential associated lesions. When this group of left-sided obstructive lesions occurs together, they are referred to as the **Shone complex.**

PATHOPHYSIOLOGY

Coarctation of the aorta can occur as a discrete juxtaductal obstruction or as tubular hypoplasia of the transverse aorta starting at one of the head or neck vessels and extending to the ductal area (previously referred to as *preductal* or *infantile-type coarctation*; Fig. 427-7). Often, both components are present. It is postulated that coarctation may be initiated in fetal life by the presence of a cardiac abnormality that results in decreased blood flow anterograde through the aortic valve (e.g., bicuspid aortic valve, VSD). Alternatively, coarctation may be caused by abnormal extension of contractile ductal tissue into the aortic wall.

In patients with discrete juxtaductal coarctation, ascending aortic blood flows through the narrowed segment to reach the descending aorta, although left ventricular hypertension and hypertrophy result. In the 1st few days of life, the PDA may serve to widen the juxtaductal area of the aorta and provide temporary relief from the obstruction. Net left-to-right ductal shunting occurs in these acyanotic infants. With more-severe juxtaductal coarctation or in the presence of transverse arch hypoplasia, right ventricular blood is ejected through the ductus to supply the descending aorta. Perfusion of the lower part of the body is then dependent on right ventricular output (see Fig. 427-7). In this situation, the femoral pulses are palpable, and differential blood pressures may not be helpful in making the diagnosis. The ductal right-to-left shunting is manifested as differential cyanosis, with the upper extremities being pink and the lower extremities blue.

Such infants may have severe pulmonary hypertension and high pulmonary vascular resistance. Signs of heart failure are prominent. Occasionally, severely hypoplastic segments of the aortic isthmus may become completely atretic and result in an interrupted aortic arch, with the left subclavian artery arising either proximal or distal to the interruption. Coarctation associated with arch hypoplasia was once referred to as infantile type because its severity usually led to recognition of the

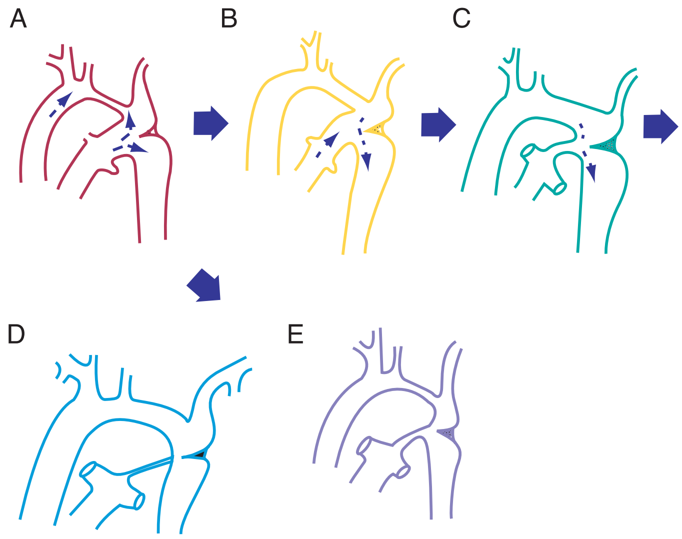

Figure 427-7 Metamorphosis of coarctation. **A,** Fetal prototype with no flow obstruction. **B,** Late gestation. The aortic ventricle increases its output and dilates the hypoplastic segment. Antegrade aortic flow bypasses the shelf via the ductal orifice. **C,** Neonate. Ductal constriction initiates the obstruction by removing the bypass and increasing antegrade arch flow. **D,** Mature juxtaductal stenosis. The bypass is completely obliterated, and intimal hypoplasia on the edge of the shelf is aggravating the stenosis. Collaterals develop. **E,** Persistence of the infantile-type fetal prototype. An intracardiac left-sided heart obstruction precludes an increase in antegrade aortic flow before or after birth. Both isthmus hypoplasia and a contraductal shelf are present. Lower body flow often depends on patency of the ductus. *(From Gersony WM: Coarctation of the aorta. condition in early infancy. Adult type referred to isolated juxtaductal coarctation, which, if mild, was not usually recognized until later childhood. These terms have been replaced with the more accurate anatomic terms describing the location and severity of the defect.

Blood pressure is elevated in the vessels that arise proximal to the coarctation; blood pressure as well as pulse pressure is lower below the constriction. The hypertension is not caused by the mechanical obstruction alone, but also involves neurohumoral mechanisms. Unless operated on in infancy, coarctation of the aorta usually results in the development of an extensive collateral circulation, chiefly from branches of the subclavian, superior intercostal, and internal mammary arteries, to create channels for arterial blood to bypass the area of coarctation. The vessels contributing to the collateral circulation may become markedly enlarged and tortuous by early adulthood.

CLINICAL MANIFESTATIONS

Coarctation of the aorta recognized after infancy is not usually associated with significant symptoms. Some children or adolescents complain about weakness or pain (or both) in the legs after exercise, but in many instances, even patients with severe coarctation are asymptomatic. Older children are frequently brought to the cardiologist's attention when they are found to be hypertensive on routine physical examination.

The classic sign of coarctation of the aorta is a disparity in pulsation and blood pressure in the arms and legs. The femoral, popliteal, posterior tibial, and dorsalis pedis pulses are weak (or absent in up to 40% of patients), in contrast to the bounding pulses of the arms and carotid vessels. The radial and femoral pulses should always be palpated simultaneously for the presence of a radial-femoral delay. Normally, the femoral pulse occurs slightly before the radial pulse. A radial-femoral delay occurs when blood flow to the descending aorta is dependent on collaterals, in which case the femoral pulse is felt after the radial pulse. In normal persons (except neonates), systolic blood pressure in the legs obtained by the cuff method is 10-20 mm Hg higher than that in the arms. In coarctation of the aorta, blood pressure in the legs is lower than that in the arms; frequently, it is difficult to obtain. This differential in blood pressures is common in patients with coarctation who are older than 1 yr, approximately 90% of whom have systolic hypertension in an upper extremity greater than the 95th percentile for age. It is important to determine the blood pressure in each arm; a pressure higher in the right than the left arm suggests involvement of the left subclavian artery in the area of coarctation. Occasionally, the right subclavian may arise anomalously from below the area of coarctation and result in a left arm pressure that is higher than the right. With exercise, a more prominent rise in systemic blood pressure occurs, and the upper-to-lower extremity pressure gradient will increase.

The precordial impulse and heart sounds are usually normal; the presence of a systolic ejection click or thrill in the suprasternal notch suggests a bicuspid aortic valve (present in 70% of cases). A short systolic murmur is often heard along the left sternal border at the 3rd and 4th intercostal spaces. The murmur is well transmitted to the left infrascapular area and occasionally to the neck. Often, the typical murmur of mild aortic stenosis can be heard in the 3rd right intercostal space. Occasionally, more significant degrees of obstruction are noted across the aortic valve. The presence of a low-pitched mid-diastolic murmur at the apex suggests mitral valve stenosis. In older patients with well-developed collateral blood flow, systolic or continuous murmurs may be heard over the left and right sides of the chest laterally and posteriorly. In these patients, a palpable thrill can occasionally be appreciated in the intercostal spaces on the back.

Neonates or infants with more severe coarctation, usually including some degree of transverse arch hypoplasia, initially have signs of lower body hypoperfusion, acidosis, and severe heart failure. These signs may be delayed days or weeks until after closure of the ductus arteriosus. If detected before ductal closure, patients may exhibit differential cyanosis, best demonstrated by simultaneous oximetry of the upper and lower extremities. On physical examination, the heart is large, and a systolic murmur is heard along the left sternal border with a loud 2nd heart sound.

DIAGNOSIS

Findings on roentgenographic examination depend on the age of the patient and on the effects of hypertension and the collateral circulation. Cardiac enlargement and pulmonary congestion are noted in infants with severe coarctation. During childhood, the findings are not striking until after the 1st decade, when the heart tends to be mildly or moderately enlarged because of left ventricular prominence. The enlarged left subclavian artery commonly produces a prominent shadow in the left superior mediastinum. **Notching** of the **inferior border of the ribs** from pressure erosion by enlarged collateral vessels is common by late childhood. In most instances, the descending aorta has an area of poststenotic dilation.

The electrocardiogram is usually normal in young children but reveals evidence of left ventricular hypertrophy in older patients. Neonates and young infants display right or biventricular hypertrophy. The segment of coarctation can generally be visualized by 2-dimensional echocardiography (Fig. 427-8); associated anomalies of the mitral and aortic valve can also be demonstrated. The descending aorta is hypopulsatile. Color Doppler is useful for demonstrating the specific site of the obstruction. Pulsed and continuous wave Doppler studies determine the pressure gradient directly at the area of coarctation; in the presence of a PDA, however, the severity of the narrowing may be underestimated. CT and MRI are valuable noninvasive tools for evaluation of coarctation when the echocardiogram is equivocal. Cardiac catheterization with selective left ventriculography and aortography is useful in occasional patients with additional anomalies and as a means of visualizing collateral blood flow. In cases that are well defined by echocardiography, CT, or MRI, diagnostic catheterization is not usually required before surgery.

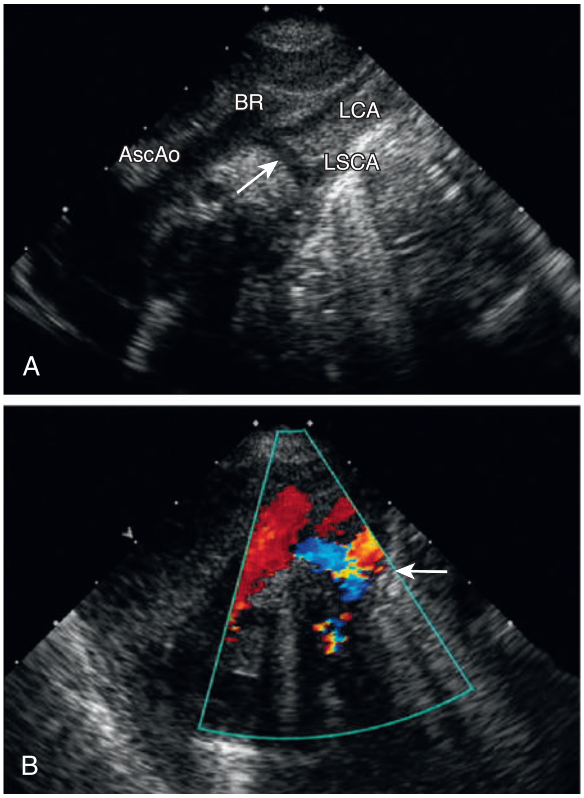

Figure 427-8 Echocardiogram demonstrating coarctation of the aorta with hypoplastic transverse arch. **A,** Suprasternal notch 2-dimensional echocardiogram showing marked narrowing beginning just distal to the brachiocephalic artery. **B,** Color Doppler demonstrates turbulent flow in the juxtaductal area *(arrow)*. AscAo, ascending aorta; BR, brachiocephalic artery; LCA, left carotid artery; LSCA, left subclavian artery.

TREATMENT

In neonates with severe coarctation of the aorta, closure of the ductus often results in hypoperfusion, acidosis, and rapid deterioration. These patients should be given an infusion of **prostaglandin E_1** to reopen the ductus and reestablish adequate lower extremity blood flow. Once a diagnosis has been confirmed and the patient stabilized, surgical repair should be performed. Older infants with heart failure but good perfusion should be managed with anticongestive measures to improve their clinical status before surgical intervention. There is usually no reason to delay surgical repair waiting for patient growth; successful repairs have been performed in small premature infants.

Older children with significant coarctation of the aorta should be treated relatively soon after diagnosis. Delay is unwarranted, especially after the 2nd decade of life, when the operation may be less successful because of decreased left ventricular function and degenerative changes in the aortic wall. Nevertheless, if cardiac reserve is sufficient, satisfactory repair is possible well into mid-adult life.

The procedure of choice for isolated juxtaductal coarctation of the aorta is controversial. Surgery remains the treatment of choice at most centers, and several surgical techniques are used. The area of coarctation can be excised and a primary re-anastomosis performed. Most often, the transverse aorta is splayed open and an "extended end-to-end" anastomosis performed to increase the effective cross-sectional area of the repair. The subclavian flap procedure, which involves division of the left subclavian artery and incorporation of it into the wall of the repaired coarctation has grown out of favor because of a higher degree of residual stenosis. Some centers favor a patch aortoplasty, in which the area of coarctation is enlarged with a roof of prosthetic material. The use of **primary angioplasty** for native coarctation remains controversial due to concern over subsequent recoarctation and aneurysm development. The use of **primary stent placement** is currently under evaluation in clinical trials and is most useful in conditions where surgical intervention may be associated with increased risk in patients with severe left ventricular dysfunction.

After surgery, a striking increase in the amplitude of pulsations in the lower extremities is noted. In the immediate postoperative course, **"rebound" hypertension** is common and requires medical management. This exaggerated acute hypertension gradually subsides and, in most patients, antihypertensive medications can be discontinued. Residual murmurs are common and may be the result of associated cardiac anomalies, of a residual flow disturbance across the repaired area, or of collateral blood flow. Rare operative problems include spinal cord injury from aortic cross-clamping if the collaterals are poorly developed, chylothorax, diaphragm injury, and laryngeal nerve injury. If a left subclavian flap approach is used, the radial pulse and blood pressure in the left arm are diminished or absent.

POSTCOARCTECTOMY SYNDROME

Postoperative **mesenteric arteritis** may be associated with acute hypertension and abdominal pain in the immediate postoperative period. The pain varies in severity and may occur in conjunction with anorexia, nausea, vomiting, leukocytosis, intestinal hemorrhage, bowel necrosis, and small bowel obstruction. Relief is usually obtained with antihypertensive drugs (nitroprusside, esmolol, captopril) and intestinal decompression; surgical exploration is rarely required for bowel obstruction or infarction.

PROGNOSIS

Although restenosis in older patients after coarctectomy is rare, a significant number of infants operated on before 1 yr of age require revision later in childhood. All patients should be monitored carefully for the development of recoarctation and an aortic anastomotic aneurysm. Should recoarctation occur, **balloon angioplasty** is the procedure of choice. In these patients, scar tissue from previous surgery may make reoperation more difficult yet makes balloon angioplasty safer because of the lower incidence of aneurysm formation. Relief of obstruction with this technique is usually excellent. **Intravascular stents** are commonly used, especially in adolescents and young adults, with generally excellent results.

Repair of coarctation in the 2nd decade of life or beyond may be associated with a higher incidence of premature cardiovascular disease, even in the absence of residual cardiac abnormalities. Early onset of adult chronic hypertension may occur, even in patients with adequately resected coarctation.

Abnormalities of the aortic valve are present in most patients. Bicuspid aortic valves are common but do not generally produce clinical signs unless the stenosis is significant. The association of a PDA and coarctation of the aorta is also common. VSDs and ASDs may be suspected by signs of a left-to-right shunt; they are exacerbated by the increased resistance to flow through the left side of the heart. Mitral valve abnormalities are also occasionally seen, as is subvalvular aortic stenosis.

Severe neurologic damage or even death may rarely occur from associated cerebrovascular disease. Subarachnoid or intracerebral hemorrhage may result from rupture of congenital aneurysms in the circle of Willis, rupture of other vessels with defective elastic and medial tissue, or rupture of normal vessels; these accidents are secondary to hypertension. Children with **PHACE syndrome** (posterior brain fossa anomalies, facial hemangiomas, arterial anomalies, cardiac anomalies and aortic coarctation, eye anomalies syndrome) may have strokes (see Table 422-2 in Chapter 422). Abnormalities of the subclavian arteries may include involvement of the left subclavian artery in the area of coarctation, stenosis of the orifice of the left subclavian artery, and anomalous origin of the right subclavian artery.

Untreated, the great majority of older patients with coarctation of the aorta would succumb between the ages of 20 and 40 yr; some live well into middle life without serious disability. The common serious complications are related to systemic hypertension, which may result in premature coronary artery disease, heart failure, hypertensive encephalopathy, or intracranial hemorrhage. Heart failure may be worsened by associated anomalies. Infective endocarditis or endarteritis is a significant complication in adults. Aneurysms of the descending aorta or the enlarged collateral vessels may develop.

427.7 Coarctation with Ventricular Septal Defect

Daniel Bernstein

Coarctation in the presence of a VSD results in both increased preload and afterload on the left ventricle, and patients with this combination of defects will be recognized either at birth or in the 1st mo of life and often have intractable cardiac failure. The magnitude of the left-to-right shunt through a VSD is dependent on the ratio of pulmonary to systemic vascular resistance. In the presence of coarctation, resistance to systemic outflow is enhanced by the obstruction, and the volume of the shunt is markedly increased. The clinical picture is that of a seriously ill infant with tachypnea, failure to thrive, and typical findings of heart failure. Often, the difference in blood pressure between the upper and lower extremities is not very marked because cardiac output may be low. Medical management should be used to stabilize the patient initially; however, it should not be used to delay corrective surgery inordinately.

In most cases, coarctation is the major anomaly causing the severe symptoms, and resection of the coarcted segment results in striking improvement. Many centers routinely repair both the VSD and coarctation at the same operation through a midline sternotomy using cardiopulmonary bypass. Some centers repair the coarctation through a left lateral thoracotomy and, at the same time, place a pulmonary artery band to decrease the ventricular-level shunt. This may be performed when a complicated VSD is present (multiple VSDs, apical muscular VSD), to avoid open heart surgery during infancy for these complex ventricular septal abnormalities.

427.8 Coarctation with Other Cardiac Anomalies and Interrupted Aortic Arch

Daniel Bernstein

Coarctation often occurs in infancy in association with other major cardiovascular anomalies, including hypoplastic left heart, severe mitral or aortic valve disease, transposition of the great arteries, and variations of double-outlet or single ventricle. The clinical manifestations depend on the effects of the associated malformations, as well as on the coarctation itself.

Coarctation of the aorta associated with severe mitral and aortic valve disease may have to be treated within the context of the hypoplastic left heart syndrome (see Chapter 431.10), even if the left ventricular chamber is not severely hypoplastic. Such patients usually have a long segment of narrow transverse aortic arch in addition to an isolated coarctation at the site of the ductus arteriosus. Coarctation of the aorta with transposition of the great arteries or single ventricle may be repaired alone or in combination with other corrective or palliative measures.

Complete interruption of the aortic arch is the most severe form of coarctation and is usually associated with other intracardiac pathology. Interruption may occur at any level, although it is most commonly seen between the left subclavian artery and the insertion of the ductus arteriosus (type A), followed in frequency by those between the left subclavian and left carotid arteries (type B), or between the left carotid and brachiocephalic arteries (type C). In newborns with an interrupted aortic arch, the ductus arteriosus provides the sole source of blood flow to the descending aorta, and differential oxygen saturations between the right arm (normal saturation) and the legs (decreased saturation) is noted. When the ductus begins to close, severe congestive heart failure, lower extremity hypoperfusion, anuria, and shock usually develop. Patients with an interrupted aortic arch can be supported with prostaglandin E_1 to keep the ductus patent before surgical repair. As one of the conotruncal malformations, an interrupted aortic arch, especially type B, can be associated with DiGeorge syndrome (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia). Cytogenetic analysis using fluorescence in situ hybridization demonstrates deletion of a segment of chromosome 22q11, known as the DiGeorge critical region.

427.9 Congenital Mitral Stenosis

Daniel Bernstein

Congenital mitral stenosis is a rare anomaly that can be isolated or associated with other defects, the most common being subvalvar and valvar aortic stenosis and coarctation of the aorta **(Shone complex).** The mitral valve may be funnel-shaped, with thickened leaflets and chordae tendineae that are shortened and deformed. Other mitral valve anomalies associated with stenosis include parachute mitral valve, caused by a single papillary muscle, and double-orifice mitral valve.

If the stenosis is moderate to severe, symptoms usually appear within the 1st yr or 2 of life. These infants have failure to thrive and various degrees of dyspnea and pallor. In some patients, wheezing may be a dominant symptom, and a misdiagnosis of bronchiolitis or reactive airway disease may have been made. Heart enlargement as a result of dilation and hypertrophy of the right ventricle and left atrium is common. Most patients have rumbling apical diastolic murmurs, but the auscultatory findings may be relatively obscure. The 2nd heart sound is loud and split. An opening snap of the mitral valve may be present. The electrocardiogram reveals right ventricular hypertrophy and may show bifid or spiked P waves indicative of left atrial enlargement. Roentgenograms usually show left atrial and right ventricular enlargement and pulmonary congestion in a perihilar or venous pattern. The echocardiogram is characteristic and shows thickened mitral valve leaflets a significant reduction of the mitral valve orifice, abnormal papillary muscle structure (or a single papillary muscle), and an enlarged left atrium with a normal or small left ventricle. A double orifice may also be visualized. Doppler studies demonstrate a mean pressure gradient across the mitral orifice. Associated anomalies such as aortic stenosis and coarctation can be evaluated. Cardiac catheterization is usually performed to confirm the transmitral pressure gradient before surgery. An increase in right ventricular, pulmonary arterial, and pulmonary capillary wedge pressure can be noted. Angiocardiography shows delayed emptying of the left atrium and the small mitral orifice.

The results of surgical treatment depend on the anatomy of the valve, but if the mitral orifice is significantly hypoplastic, reduction of the gradient may be difficult. In some patients, a mitral valve prosthesis is required, and if the valve orifice is too small, the prosthesis may be placed in the supramitral position. However, whatever prosthesis is used, it must be replaced serially as the child grows. These patients must be managed by anticoagulation with warfarin, and complications of excessive and insufficient anticoagulation are fairly common in infancy. Transcatheter balloon valvuloplasty has been used as a palliative procedure with disappointing results, except in the situation of rheumatic mitral stenosis.

Bibliography is available at Expert Consult.

427.10 Pulmonary Venous Hypertension

Daniel Bernstein

A variety of lesions may give rise to chronic pulmonary venous hypertension, which when extreme may result in pulmonary arterial hypertension and right-sided heart failure. These lesions include congenital mitral stenosis, mitral insufficiency, total anomalous pulmonary venous return with obstruction, left atrial myxomas, cor triatriatum (stenosis of a common pulmonary vein), individual pulmonary vein stenosis, and supravalvular mitral rings. Early symptoms can be confused with chronic pulmonary disease such as asthma because of a lack of specific cardiac findings on physical examination. Subtle signs of pulmonary hypertension may be present. The electrocardiogram shows right ventricular hypertrophy with spiked P waves. Roentgenographic studies reveal cardiac enlargement and prominence of the pulmonary veins in the hilar region, the right ventricle and atrium, and the main pulmonary artery; the left atrium is normal in size or only slightly enlarged.

The echocardiogram may demonstrate left atrial myxoma, cor triatriatum, stenosis of one or more pulmonary veins, or a mitral valve abnormality, especially supravalvar mitral ring. Cardiac catheterization excludes the presence of a shunt and demonstrates pulmonary hypertension with elevated pulmonary arterial wedge pressure. Left atrial pressure is normal if the lesion is at the level of the pulmonary veins, but it is elevated if the lesion is at the level of the mitral valve. Selective pulmonary arteriography usually delineates the anatomic lesion. Cor triatriatum, left atrial myxoma, and supravalvular mitral rings can all be successfully managed surgically.

The **differential diagnosis** includes pulmonary venoocclusive disease, an idiopathic process that produces obstructive lesions in 1 or more pulmonary veins. The cause is uncertain and disease that begins in 1 vein can spread to others. Although it is usually encountered in patients after repair of obstructed total anomalous pulmonary venous return (see Chapter 431.7), it can occur in the absence of congenital heart disease. The patient initially presents with left-sided heart failure on the basis of congested lungs with apparent pulmonary edema. Dyspnea, fatigue, and pleural effusions are common. Left atrial pressure is normal, but pulmonary arterial wedge pressure is usually elevated. A normal wedge pressure may be encountered if collaterals have formed or the wedge recording is performed in an uninvolved segment. Angiographically, the pulmonary veins return normally to the left atrium, but 1 or more pulmonary veins are narrowed, either focally or diffusely.

Studies using lung biopsy have demonstrated pulmonary venous and, occasionally, arterial involvement. Pulmonary veins and venules demonstrate fibrous narrowing or occlusion, and pulmonary artery thrombi may be present. Attempts at surgical repair, balloon dilation, and transcatheter stenting have not significantly improved the generally poor prognosis of these patients. Clinical trials of antiproliferative chemotherapy are currently in progress. Combined heart-lung transplantation (see Chapter 443.2) is often the only alternative therapeutic option.

Chapter **428**

Acyanotic Congenital Heart Disease: Regurgitant Lesions

428.1 Pulmonary Valvular Insufficiency and Congenital Absence of the Pulmonary Valve

Daniel Bernstein

Pulmonary valvular insufficiency most often accompanies other cardiovascular diseases or may be secondary to severe pulmonary hypertension. Incompetence of the valve is an expected result after surgery for right ventricular outflow tract obstruction, for example, pulmonary valvotomy in patients with valvular pulmonic stenosis or valvotomy with infundibular resection in patients with tetralogy of Fallot. Isolated congenital insufficiency of the pulmonary valve is rare. These patients are usually asymptomatic because the insufficiency is generally mild.

The prominent physical sign is a decrescendo diastolic murmur at the upper and midleft sternal border, which has a lower pitch than the murmur of aortic insufficiency because of the lower pressure involved. Radiographs of the chest show prominence of the main pulmonary artery and, if the insufficiency is severe, right ventricular enlargement. The electrocardiogram is normal or shows minimal right ventricular hypertrophy. Pulsed and color Doppler studies demonstrate retrograde flow from the pulmonary artery to the right ventricle during diastole. Cardiac magnetic resonance angiography is useful for quantifying both right ventricular volume and the regurgitant fraction. Isolated pulmonary valvular insufficiency is generally well tolerated and does not require surgical treatment. When pulmonary insufficiency is severe, especially if significant tricuspid insufficiency has begun to develop, replacement with a homograft valve may become necessary to preserve right ventricular function.

Congenital absence of the pulmonary valve is usually associated with a ventricular septal defect, often in the context of tetralogy of Fallot (see Chapter 430.1). In many of these neonates, the pulmonary arteries become widely dilated and compress the bronchi, with subsequent recurrent episodes of wheezing, pulmonary collapse, and pneumonitis. The presence and degree of cyanosis are variable. Florid pulmonary valvular incompetence may not be well tolerated, and death may occur from a combination of bronchial compression, hypoxemia, and heart failure. Correction involves plication of the massively dilated pulmonary arteries, closure of the ventricular septal defect, and placement of a homograft across the right ventricular outflow tract.

Bibliography is available at Expert Consult.

428.2 Congenital Mitral Insufficiency

Daniel Bernstein

Congenital mitral insufficiency is rare as an isolated lesion and is more often associated with other anomalies. It is most commonly encountered in combination with an atrioventricular septal defect, either an ostium primum defect, or a complete atrioventricular septal defect (see Chapter 426.5). Mitral insufficiency is also seen in patients with dilated cardiomyopathy (see Chapter 439.1) as their left ventricular function deteriorates, secondary to dilation of the valve ring. Mitral insufficiency may also be encountered in conjunction with coarctation of the aorta, ventricular septal defect, corrected transposition of the great vessels, anomalous origin of the left coronary artery from the pulmonary artery, or Marfan syndrome. In the absence of other congenital heart disease, endocarditis or rheumatic fever should be suspected in a patient with isolated severe mitral insufficiency (Table 428-1).

In isolated mitral insufficiency, the mitral valve annulus is usually dilated, the chordae tendineae are short and may insert anomalously, and the valve leaflets are deformed. When mitral insufficiency is severe enough to cause clinical symptoms, the left atrium enlarges as a result of the regurgitant flow, and the left ventricle becomes hypertrophied and dilated. Pulmonary venous pressure is increased, and the increased pressure ultimately results in pulmonary hypertension and right ventricular hypertrophy and dilation. Mild lesions produce no symptoms;

Table 428-1 Causes and Mechanisms of Mitral Regurgitation

	Organic			Functional
	TYPE I*	TYPE II†	TYPE IIIA‡	TYPE I*/TYPE IIIB‡
Nonischemic	Endocarditis (perforation); degenerative (annular calcification); congenital (cleft leaflet)	Degenerative (billowing/flail leaflets); endocarditis (ruptured chordae); traumatic (ruptured chord/PM); rheumatic (acute RF)	Rheumatic (chronic RF); iatrogenic (radiation/drug); inflammatory (lupus/anticardiolipin), eosinophilic (endocardial disease, endomyocardial fibrosis)	Cardiomyopathy; myocarditis; left-ventricular dysfunction (any cause)

MR, mitral regurgitation; PM, papillary muscle; RF, rheumatic fever.
*Mechanism involves normal leaflet movement.
†Mechanism involves excessive valve movement.
‡Restricted valve movement, IIIa in diastole, IIIb in systole.

the only abnormal sign is the apical holosystolic murmur of mitral regurgitation. Severe regurgitation results in symptoms that can appear at any age, including poor physical development, frequent respiratory infections, fatigue on exertion, and episodes of pulmonary edema or congestive heart failure. Often, a diagnosis of reactive airway disease will have been made because of the similarity in pulmonary symptoms, including wheezing, which may be a dominant finding in infants and young children.

The typical murmur of mitral insufficiency is a high-pitched, apical holosystolic murmur. If the insufficiency is moderate to severe, it is usually associated with a low-pitched, apical mid-diastolic rumbling murmur indicative of increased diastolic flow across the mitral valve. The pulmonary component of the 2nd heart sound will be accentuated in the presence of pulmonary hypertension. The electrocardiogram usually shows bifid P waves consistent with left atrial enlargement, signs of left ventricular hypertrophy, and sometimes signs of right ventricular hypertrophy. Radiographic examination shows enlargement of the left atrium, which at times is massive. The left ventricle is prominent, and pulmonary vascularity is normal or prominent. The echocardiogram demonstrates the enlarged left atrium and ventricle. Color Doppler demonstrates the extent of the insufficiency, and pulsed Doppler of the pulmonary veins detects retrograde flow when mitral insufficiency is severe. Cardiac catheterization shows elevated left atrial pressure. Pulmonary artery hypertension of varying severity may be present. Selective left ventriculography reveals the severity of mitral regurgitation.

Mitral valvuloplasty can result in striking improvement in symptoms and heart size, but in some patients, installation of a prosthetic mechanical mitral valve may be necessary. Before surgery, associated anomalies must be identified.

428.3 Mitral Valve Prolapse

Daniel Bernstein

Mitral valve prolapse results from an abnormal mitral valve mechanism that causes billowing of one or both mitral leaflets, especially the posterior cusp, into the left atrium toward the end of systole. The abnormality is predominantly congenital but may not be recognized until adolescence or adulthood. Mitral valve prolapse is usually sporadic, is more common in girls, and may be inherited as an autosomal dominant trait with variable expression. It is common in patients with Marfan syndrome, straight back syndrome, pectus excavatum, scoliosis, Ehlers-Danlos syndrome, osteogenesis imperfecta, and pseudoxanthoma elasticum. The dominant abnormal signs are auscultatory, although occasional patients may have chest pain or palpitations. The apical murmur is late systolic and may be preceded by a click, but these signs may vary in the same patient and, at times, only the click is audible. In the standing or sitting position, the click may occur earlier in systole, and the murmur may be more prominent in late systole. Arrhythmias may occur and are primarily unifocal or multifocal premature ventricular contractions.

The electrocardiogram is usually normal but may show biphasic T waves, especially in leads II, III, aVF, and V_6; the T-wave abnormalities may vary at different times in the same patient. The chest roentgenogram is normal. The echocardiogram shows a characteristic posterior movement of the posterior mitral leaflet during mid- or late systole or demonstrates pansystolic prolapse of both the anterior and posterior mitral leaflets. These echocardiographic findings must be interpreted cautiously because the appearance of minimal mitral prolapse may be a normal variant. Prolapse is more precisely defined by single or bileaflet prolapse of >2 mm beyond the long axis annular plane with or without leaflet thickening. Prolapse with valve thickening >5 mm is "classic"; a lesser degree is "nonclassic." Two-dimensional real-time echocardiography shows that both the free edge and the body of the mitral leaflets move posteriorly in systole toward the left atrium. Doppler can assess the presence and severity of mitral regurgitation.

This lesion is not progressive in childhood, and specific therapy is not indicated. Antibiotic prophylaxis is no longer recommended during surgery and dental procedures (see Chapter 437).

Adults (men more often than women) with mitral valve prolapse are at increased risk for cardiovascular complications (sudden death, arrhythmia, cerebrovascular accidents, progressive valve dilation, heart failure, and endocarditis) in the presence of **thickened** (>5 mm) and **redundant** mitral valve leaflets. Risk factors for morbidity also include poor left ventricular function, moderate to severe mitral regurgitation, and left atrial enlargement.

Often, confusion exists concerning the diagnosis of mitral valve prolapse. The high frequency of mild prolapse on the echocardiogram in the absence of clinical findings suggests that, in these cases, true mitral valve prolapse syndrome is not present. These patients and their parents should be reassured of this fact, and no special recommendations should be made regarding management or frequent laboratory studies.

428.4 Tricuspid Regurgitation

Daniel Bernstein

Isolated tricuspid regurgitation is generally associated with Ebstein anomaly of the tricuspid valve. Ebstein anomaly may occur either without cyanosis or with varying degrees of cyanosis, depending on the severity of the tricuspid regurgitation and the presence of an atrial-level communication (patent foramen ovale or atrial septal defect). Older children tend to have the acyanotic form, whereas if detected in the newborn period, Ebstein anomaly is usually associated with severe cyanosis (see Chapter 430.7).

Tricuspid regurgitation often accompanies right ventricular dysfunction. When the right ventricle becomes dilated because of volume overload or intrinsic myocardial disease, or both, the tricuspid annulus also enlarges, with resultant valve insufficiency. This form of regurgitation may improve if the cause of the right ventricular dilation is corrected, or it may require surgical plication of the valve annulus. Tricuspid regurgitation is also encountered in newborns with perinatal asphyxia. The cause may be related to an increased susceptibility of the papillary muscles to ischemic damage and subsequent transient papillary muscle dysfunction. Finally, tricuspid regurgitation is seen in up to 30% of children after heart transplantation, which can be a risk factor for graft dysfunction but is also seen as a consequence of valve injury as a result of endomyocardial biopsy.

Cyanotic Congenital Heart Disease: Evaluation of the Critically Ill Neonate with Cyanosis and Respiratory Distress

Daniel Bernstein

See also Chapter 101.

A severely ill neonate with cardiorespiratory distress and cyanosis is a diagnostic challenge. The clinician must perform a rapid evaluation to determine whether congenital heart disease is a cause so that potentially lifesaving measures can be instituted. The differential diagnosis of neonatal cyanosis is presented in Table 101-1 in Chapter 101.

CARDIAC DISEASE LEADING TO CYANOSIS

Congenital heart disease produces cyanosis when obstruction to right ventricular outflow causes intracardiac right-to-left shunting or when complex anatomic defects, many unassociated with pulmonary stenosis, cause an admixture of pulmonary and systemic venous return in the heart. Cyanosis from pulmonary edema may also develop in patients with heart failure caused by left-to-right shunts, although the degree is usually less severe. Cyanosis may be caused by persistence of fetal pathways, for example, right-to-left shunting across the foramen ovale and ductus arteriosus in the presence of pulmonary outflow tract obstruction or persistent pulmonary hypertension of the newborn (PPHN) (see Chapter 101.7).

DIFFERENTIAL DIAGNOSIS

The **hyperoxia test** is 1 method of distinguishing cyanotic congenital heart disease from pulmonary disease. Neonates with cyanotic congenital heart disease are usually not able to significantly raise their arterial Pao_2 during administration of 100% oxygen. If the Pao_2 rises above 150 mm Hg during 100% oxygen administration, an intracardiac right-to-left shunt can usually be excluded, although this is not 100% confirmative, as some patients with cyanotic congenital heart lesions may be able to increase their Pao_2 to >150 mm Hg because of favorable intracardiac streaming patterns. In patients with pulmonary disease, Pao_2 generally increases significantly with 100% oxygen as ventilation-perfusion inequalities are overcome. In infants with cyanosis from a central nervous system disorder, the Pao_2 usually normalizes completely during artificial ventilation. Hypoxia in many heart lesions is profound and constant, whereas in respiratory disorders and in PPHN, arterial oxygen tension often varies with time or changes in ventilator management. Hyperventilation may improve the hypoxia in neonates with PPHN and only occasionally in those with cyanotic congenital heart disease.

Although a significant heart murmur usually suggests a cardiac basis for the cyanosis, several of the more severe cardiac defects (transposition of the great vessels) may not initially be associated with a murmur.

The chest roentgenogram may be helpful in the differentiation of pulmonary and cardiac disease; in the latter, it indicates whether pulmonary blood flow is increased, normal, or decreased.

Two-dimensional echocardiography is the definitive noninvasive test to determine the presence of congenital heart disease. Cardiac catheterization is less often used for diagnostic purposes, and is usually performed to examine structures that are sometime less well visualized by echocardiography, such as distal branch pulmonary arteries or aortopulmonary collateral arteries in patients with tetralogy of Fallot with pulmonary atresia (see Chapter 430.2), coronary arteries and right ventricular sinusoids in patients with pulmonary atresia and intact ventricular septum (see Chapter 430.3). If echocardiography is not immediately available, the clinician caring for a newborn with possible cyanotic heart disease should not hesitate to start a prostaglandin infusion (for a possible ductal-dependent lesion). Because of the risk of hypoventilation associated with prostaglandins, a practitioner skilled in neonatal endotracheal intubation must be available.

Chapter 430

Cyanotic Congenital Heart Lesions: Lesions Associated with Decreased Pulmonary Blood Flow

430.1 Tetralogy of Fallot

Daniel Bernstein

Tetralogy of Fallot is one of the conotruncal family of heart lesions in which the primary defect is an anterior deviation of the infundibular septum (the muscular septum that separates the aortic and pulmonary outflows). The consequences of this deviation are the 4 components: (1) obstruction to right ventricular outflow (pulmonary stenosis), (2) a malalignment type of ventricular septal defect (VSD), (3) dextroposition of the aorta so that it overrides the ventricular septum, and (4) right ventricular hypertrophy (Fig. 430-1). Obstruction to pulmonary arterial blood flow is usually at both the right ventricular infundibulum (subpulmonic area) and the pulmonary valve. The main pulmonary artery may be small, and various degrees of branch pulmonary artery stenosis may be present. Complete obstruction of right ventricular outflow (tetralogy with pulmonary atresia) is classified as an extreme form of tetralogy of Fallot (see Chapter 430.2). The degree of pulmonary outflow obstruction determines the degree of the patient's cyanosis and the age of first presentation.

PATHOPHYSIOLOGY

The pulmonary valve annulus may range from being nearly normal in size to being severely hypoplastic. The valve itself is often bicuspid or unicuspid and, occasionally, is the only site of stenosis. More commonly, the subpulmonic or infundibular muscle, known as the *crista supraventricularis,* is hypertrophic, which contributes to the subvalvar stenosis and results in an infundibular chamber of variable size and contour. When the right ventricular outflow tract is completely

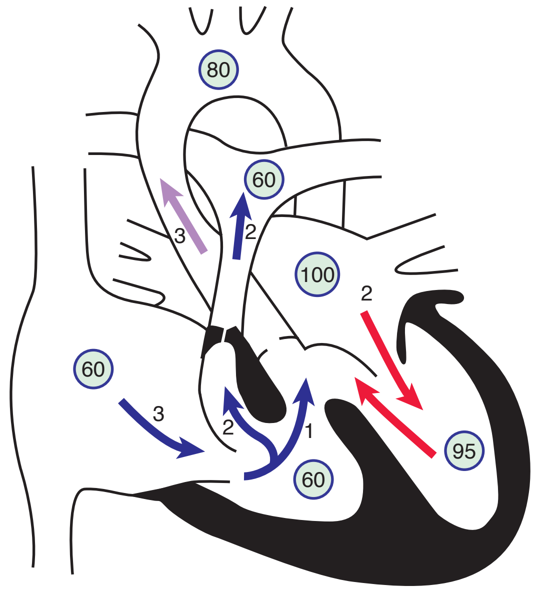

Figure 430-1 Physiology of the tetralogy of Fallot. *Circled numbers* represent oxygen saturation values. The *numbers next to the arrows* represent volumes of blood flow (in L/min/m^2). Atrial (mixed venous) oxygen saturation is decreased because of the systemic hypoxemia. A volume of 3 L/min/m^2 of desaturated blood enters the right atrium and traverses the tricuspid valve. Two liters flows through the right ventricular outflow tract into the lungs, whereas 1 L shunts right to left through the ventricular septal defect (VSD) into the ascending aorta. Thus, pulmonary blood flow is two-thirds normal (Qp : Qs [pulmonary-to-systemic blood flow ratio] of 0.7 : 1). Blood returning to the left atrium is fully saturated. Only 2 L of blood flows across the mitral valve. Oxygen saturation in the left ventricle may be slightly decreased because of right-to-left shunting across the VSD. Two liters of saturated left ventricular blood mixing with 1 L of desaturated right ventricular blood is ejected into the ascending aorta. Aortic saturation is decreased, and cardiac output is normal.

obstructed **(pulmonary atresia),** the anatomy of the branch pulmonary arteries is extremely variable. A main pulmonary artery segment may be in continuity with right ventricular outflow, separated by a fibrous but imperforate pulmonary valve; the main pulmonary artery may be moderately or severely hypoplastic but still supply part or all of the pulmonary bed; or the entire main pulmonary artery segment may be absent. Occasionally, the branch pulmonary arteries may be discontinuous. Pulmonary blood flow may be supplied by a patent ductus arteriosus (PDA) or by multiple **major aortopulmonary collateral arteries (MAPCAs)** arising from the ascending and/or descending aorta and supplying various lung segments.

The VSD is usually nonrestrictive and large, is located just below the aortic valve, and is related to the posterior and right aortic cusps. Rarely, the VSD may be in the inlet portion of the ventricular septum (atrioventricular septal defect). The normal fibrous continuity of the mitral and aortic valves is usually maintained, and if not (because of the presence of a subaortic muscular conus) the classification is usually that of double-outlet right ventricle (see Chapter 430.5). The aortic arch is right sided in 20% of cases, and the aortic root is usually large and overrides the VSD to varying degrees. When the aorta overrides the VSD by more than 50% and if there is a subaortic conus, this defect is classified as a form of double-outlet right ventricle; however, the circulatory dynamics are the same as that of tetralogy of Fallot.

Systemic venous return to the right atrium and right ventricle is normal. When the right ventricle contracts in the presence of marked pulmonary stenosis, blood is shunted across the VSD into the aorta. Persistent arterial desaturation and cyanosis result, the degree dependent on the severity of the pulmonary obstruction. Pulmonary blood flow, when severely restricted by the obstruction to right ventricular outflow, may be supplemented by a PDA. Peak systolic and diastolic pressures in each ventricle are similar and at systemic level. A large pressure gradient occurs across the obstructed right ventricular outflow tract, and pulmonary arterial pressure is either normal or lower than normal. The degree of right ventricular outflow obstruction determines the timing of the onset of symptoms, the severity of cyanosis, and the degree of right ventricular hypertrophy. When obstruction to right ventricular outflow is mild to moderate and a balanced shunt is present across the VSD, the patient may not be visibly cyanotic (**acyanotic** or **"pink"** tetralogy of Fallot). When obstruction is severe, cyanosis will be present from birth and worsen when the ductus arteriosus begins to close.

CLINICAL MANIFESTATIONS

Infants with mild degrees of right ventricular outflow obstruction may initially be seen with heart failure caused by a ventricular-level left-to-right shunt. Often, cyanosis is not present at birth; but with increasing hypertrophy of the right ventricular infundibulum as the patient grows, cyanosis occurs later in the 1st yr of life. In infants with severe degrees of right ventricular outflow obstruction, neonatal cyanosis is noted immediately. In these infants, pulmonary blood flow may be partially or nearly totally dependent on flow through the ductus arteriosus. When the ductus begins to close in the 1st few hr or days of life, severe cyanosis and circulatory collapse may occur. Older children with long-standing cyanosis who have not undergone surgery may have dusky blue skin, gray sclerae with engorged blood vessels, and marked clubbing of the fingers and toes. Chapter 434 describes the extracardiac manifestations of long-standing cyanotic congenital heart disease.

In older children with unrepaired tetralogy, dyspnea occurs on exertion. They may play actively for a short time and then sit or lie down. Older children may be able to walk a block or so before stopping to rest. Characteristically, children assume a squatting position for the relief of dyspnea caused by physical effort; the child is usually able to resume physical activity after a few minutes of squatting. These findings occur most often in patients with significant cyanosis at rest.

Paroxysmal hypercyanotic attacks (hypoxic, **"blue,"** or **"tet" spells**) are a particular problem during the 1st 2 yr of life. The infant becomes hyperpneic and restless, cyanosis increases, gasping respirations ensue, and syncope may follow. The spells occur most frequently in the morning on initially awakening or after episodes of vigorous crying. Temporary disappearance or a decrease in intensity of the systolic murmur is usual as flow across the right ventricular outflow tract diminishes. The spells may last from a few minutes to a few hours. Short episodes are followed by generalized weakness and sleep. Severe spells may progress to unconsciousness and, occasionally, to convulsions or hemiparesis. The onset is usually spontaneous and unpredictable. Spells are associated with reduction of an already compromised pulmonary blood flow, which, when prolonged, results in severe systemic hypoxia and metabolic acidosis. Infants who are only mildly cyanotic at rest are often more prone to the development of hypoxic spells because they have not acquired the homeostatic mechanisms to tolerate rapid lowering of arterial oxygen saturation, such as polycythemia.

Depending on the frequency and severity of hypercyanotic attacks, 1 or more of the following procedures should be instituted in sequence: (1) placement of the infant on the abdomen in the knee-chest position while making certain that the infant's clothing is not constrictive, (2) administration of oxygen (although increasing inspired oxygen will not reverse cyanosis caused by intracardiac shunting), and (3) injection of morphine subcutaneously in a dose not in excess of 0.2 mg/kg. Calming and holding the infant in a knee-chest position may abort progression of an early spell. Premature attempts to obtain blood samples may cause further agitation and be counterproductive.

Because metabolic acidosis develops when arterial Po_2 is <40 mm Hg, rapid correction (within several minutes) with intravenous administration of sodium bicarbonate is necessary if the spell is unusually severe and the child shows a lack of response to the foregoing therapy. Recovery from the spell is usually rapid once the pH has returned to normal. Repeated blood pH measurements may be necessary because rapid

recurrence of acidosis may ensue. For spells that are resistant to this therapy, intubation and sedation are often sufficient to break the spell. Drugs that increase systemic vascular resistance, such as intravenous phenylephrine, can improve right ventricular outflow, decrease the right-to-left shunt, and improve the symptoms. β-Adrenergic blockade by the intravenous administration of propranolol (0.1 mg/kg given slowly to a maximum of 0.2 mg/kg) has also been used. Growth and development may be delayed in patients with severe untreated tetralogy of Fallot, particularly when their oxygen saturation is chronically <70%. Puberty may also be delayed in patients who have not undergone surgery.

The pulse is usually normal, as are venous and arterial pressures. In older infants and children, the left anterior hemithorax may bulge anteriorly because of long-standing right ventricular hypertrophy. A substernal right ventricular impulse can usually be detected. A systolic thrill may be felt along the left sternal border in the 3rd and 4th parasternal spaces. The systolic murmur is usually loud and harsh; it may be transmitted widely, especially to the lungs, but is most intense at the left sternal border. The murmur is generally ejection in quality at the upper sternal border, but it may sound more holosystolic toward the lower sternal border. It may be preceded by a click. The murmur is caused by turbulence through the right ventricular outflow tract. It tends to become louder, longer, and harsher as the severity of pulmonary stenosis increases from mild to moderate; however, it can actually become less prominent with severe obstruction, especially during a hypercyanotic spell due to shunting of blood away from the right ventricular outflow through the aortic valve. Either the 2nd heart sound is single, or the pulmonic component is soft. Infrequently, a continuous murmur may be audible, especially if prominent collaterals are present.

DIAGNOSIS

The typical radiologic configuration as seen in the anteroposterior view consists of a narrow base, concavity of the left heart border in the area usually occupied by the pulmonary artery, and normal overall heart size. The hypertrophied right ventricle causes the rounded apical shadow to be uptilted so that it is situated higher above the diaphragm than normal and pointing horizontally to the left chest wall. The cardiac silhouette has been likened to that of a boot ("coeur en sabot") (Fig. 430-2). The hilar areas and lung fields are relatively clear because of diminished pulmonary blood flow or the small size of the pulmonary arteries, or both. The aorta is usually large, and in approximately 20% of patients it arches to the right, which results in an indentation of the leftward-positioned air-filled tracheobronchial shadow in the anteroposterior view.

The electrocardiogram demonstrates right axis deviation and evidence of right ventricular hypertrophy. A dominant R wave appears in the right precordial chest leads (Rs, R, qR, qRs) or an RSR′ pattern. In some cases, the only sign of right ventricular hypertrophy may initially be a positive T wave in leads V_3R and V_1. The P wave is tall and peaked suggesting right atrial enlargement (see Fig. 423-6 in Chapter 423).

Two-dimensional echocardiography establishes the diagnosis (Fig. 430-3) and provides information about the extent of aortic override of the septum, the location and degree of the right ventricular outflow tract obstruction, the size of the pulmonary valve annulus and main and proximal branch pulmonary arteries, and the side of the aortic arch. The echocardiogram is also useful in determining whether a PDA is supplying a portion of the pulmonary blood flow. In a patient without pulmonary atresia, echocardiography usually obviates the need for catheterization before surgical repair. However, in patients with pulmonary atresia, catheterization is necessary to image the source of blood supply to and size of each lung segment.

Cardiac catheterization demonstrates a systolic pressure in the right ventricle equal to the systemic pressure, since the right ventricle is connected directly to the overriding aorta. If the pulmonary artery is entered, the pressure is markedly decreased, although crossing the right ventricular outflow tract, especially in severe cases, may precipitate a tet spell. Pulmonary arterial pressure is usually lower than normal, in the range of 5-10 mm Hg. The level of arterial oxygen saturation depends on the magnitude of the right-to-left shunt; in "pink tets," the systemic oxygen saturation may be normal, whereas in a moderately cyanotic patient at rest, it is usually 75-85%.

Selective right ventriculography will demonstrate all of the anatomical features. Contrast medium outlines the heavily trabeculated right ventricle. The infundibular stenosis varies in length, width, contour, and distensibility (Fig. 430-4). The pulmonary valve is usually thickened, and the annulus may be small. In patients with pulmonary atresia and VSD, echocardiography alone is not adequate to assess the anatomy of the pulmonary arteries and MAPCAs. Cardiac CT is extremely helpful, and cardiac catheterization with injection into each arterial collateral is indicated. Complete and accurate information regarding the size and peripheral distribution of the main pulmonary arteries and any collateral vessels (MAPCAs) is important when evaluating these children as surgical candidates.

Aortography or coronary arteriography outlines the course of the coronary arteries. In 5-10% of patients with the tetralogy of Fallot, coronary artery abnormalities may be present, most commonly an aberrant coronary artery crossing over the right ventricular outflow

Figure 430-2 Chest x-ray of an 8 yr old boy with the tetralogy of Fallot. Note the normal heart size, some elevation of the cardiac apex, concavity in the region of the main pulmonary artery, right-sided aortic arch, and diminished pulmonary vascularity.

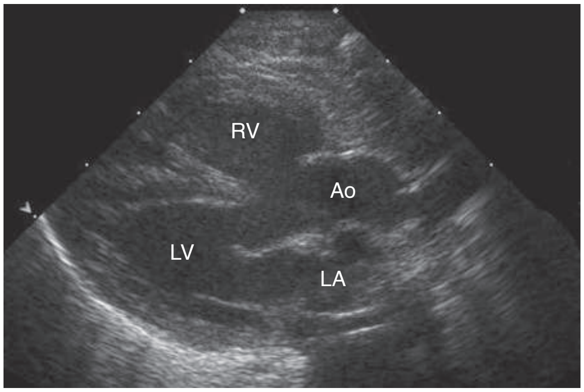

Figure 430-3 Echocardiogram in a patient with the tetralogy of Fallot. This parasternal long-axis 2-dimensional view demonstrates anterior displacement of the outflow ventricular septum that resulted in stenosis of the subpulmonic right ventricular outflow tract, overriding of the aorta, and an associated ventricular septal defect. Ao, overriding aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

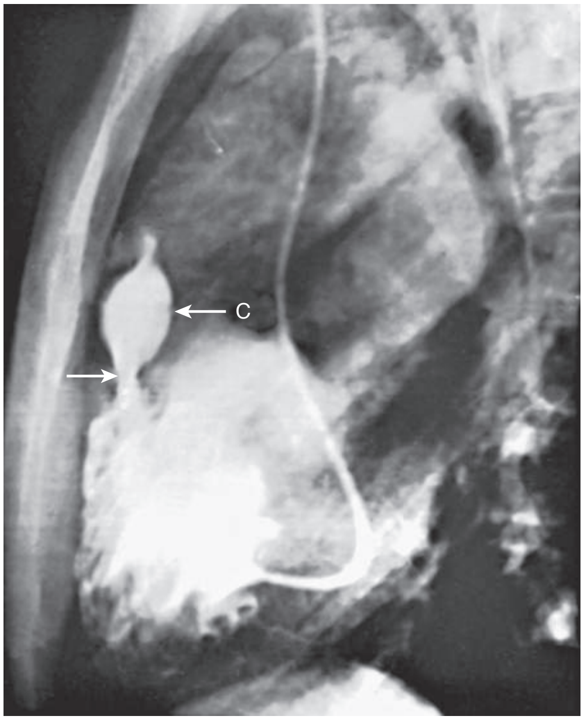

Figure 430-4 Lateral view of a selective right ventriculogram in a patient with the tetralogy of Fallot. The *arrow* points to an infundibular stenosis that is below the infundibular chamber *(C)*. The narrowed pulmonary valve orifice is seen at the distal end of the infundibular chamber.

tract; this artery must not be cut during surgical repair. Verification of normal coronary arteries is important when considering surgery in young infants who may need a patch across the pulmonary valve annulus. Echocardiography can usually delineate the coronary artery anatomy; angiography is reserved for cases in which questions remain.

COMPLICATIONS

Before the age of corrective surgery, patients with tetralogy of Fallot were susceptible to several serious complications. For this reason, most children undergo complete repair (or in some cases palliation) in the 1st few mo of life; consequently, these complications are now rare. **Cerebral thromboses,** usually occurring in the cerebral veins or dural sinuses and occasionally in the cerebral arteries, are a sequelae of extreme polycythemia and dehydration. Thromboses occur most often in patients younger than 2 yr. These patients may have iron-deficiency anemia, frequently with hemoglobin and hematocrit levels in the normal range (but too low for cyanotic heart disease). Therapy consists of adequate hydration and supportive measures. Phlebotomy and volume replacement with albumin or saline are indicated in extremely **polycythemic** patients who are symptomatic.

Brain abscess is less common than cerebral vascular events and extremely rare today. Patients with a brain abscess are usually older than 2 yr. The onset of the illness is often insidious and consists of low-grade fever or a gradual change in behavior, or both. Some patients have an acute onset of symptoms that may develop after a recent history of headache, nausea, and vomiting. Seizures may occur; localized neurologic signs depend on the site and size of the abscess and the presence of increased intracranial pressure. CT or MRI confirms the diagnosis. Antibiotic therapy may help keep the infection localized, but surgical drainage of the abscess is usually necessary (see Chapter 604).

Bacterial endocarditis may occur in the right ventricular infundibulum or on the pulmonic, aortic, or, rarely, tricuspid valves. Endocarditis may complicate palliative shunts or, in patients with corrective surgery, any residual pulmonic stenosis or VSD. Heart failure is not a usual feature in patients with tetralogy of Fallot, with the exception of some young infants with "pink" or acyanotic tetralogy of Fallot. As the degree of pulmonary obstruction worsens with age, the symptoms of heart failure resolve and eventually the patient experiences cyanosis often by 6-12 mo of age. These patients are at increased risk for hypercyanotic spells at this time.

ASSOCIATED ANOMALIES

A PDA may be present, and defects in the atrial septum are occasionally seen. A right aortic arch occurs in ≈20% of patients, and other anomalies of the pulmonary arteries and aortic arch may also be seen. Persistence of a left superior vena cava draining into the coronary sinus is common but not a concern. Multiple VSDs are occasionally present and must be diagnosed before corrective surgery. Coronary artery anomalies are present in 5-10% and can complicate surgical repair. Tetralogy of Fallot may also occur with an atrioventricular septal defect, often associated with Down syndrome.

Congenital absence of the pulmonary valve produces a distinct syndrome that is usually marked by signs of upper airway obstruction (see Chapter 428.1). Cyanosis may be absent, mild, or moderate; the heart is large and hyperdynamic; and a loud to-and-fro murmur is present. Marked aneurysmal dilation of the main and branch pulmonary arteries results in compression of the bronchi and then produces stridulous or wheezing respirations and recurrent pneumonia. If the airway obstruction is severe, reconstruction of the trachea at the time of corrective cardiac surgery may be required to alleviate the symptoms.

Absence of a branch pulmonary artery, most often the left, should be suspected if the roentgenographic appearance of the pulmonary vasculature differs on the 2 sides; absence of a pulmonary artery is often associated with hypoplasia of the affected lung. It is important to recognize the absence of a pulmonary artery because occlusion of the remaining pulmonary artery during surgery seriously compromises the already reduced pulmonary blood flow.

As 1 of the conotruncal malformations, tetralogy of Fallot can be associated with **DiGeorge syndrome** or **Shprintzen velocardiofacial syndrome**, also known by the acronym **CATCH 22** (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia). Cytogenetic analysis using fluorescence in situ hybridization demonstrates deletions of a large segment of chromosome 22q11.2 known as the *DiGeorge critical region.* Deletion or mutation of the gene encoding the transcription factor *Tbx1* has been implicated as a possible cause of DiGeorge syndrome, although several other genes have been identified as possible candidates or modifier genes.

TREATMENT

Treatment of tetralogy of Fallot depends on the severity of the right ventricular outflow tract obstruction. Infants with severe tetralogy require urgent medical treatment and surgical intervention in the neonatal period. Therapy is aimed at providing an immediate increase in pulmonary blood flow to prevent the sequelae of severe hypoxia. The infant should be transported to a medical center adequately equipped to evaluate and treat neonates with congenital heart disease under optimal conditions. Prolonged, severe hypoxia may lead to shock, respiratory failure, and intractable acidosis and will significantly reduce the chance of survival, even when surgically amenable lesions are present. It is critical that normal body temperature be maintained during the transfer because cold increases oxygen consumption, which places additional stress on a cyanotic infant, whose oxygen delivery is already limited. Blood glucose levels should be monitored because hypoglycemia is more likely to develop in infants with cyanotic heart disease.

Neonates with marked right ventricular outflow tract obstruction may deteriorate rapidly because, as the ductus arteriosus begins to close, pulmonary blood flow is further compromised. The intravenous administration of prostaglandin E_1 (0.01-0.20 μg/kg/min), a potent and specific relaxant of ductal smooth muscle, causes dilation of the ductus arteriosus and usually provides adequate pulmonary blood flow

until a surgical procedure can be performed. This agent should be administered intravenously as soon as cyanotic congenital heart disease is clinically suspected and continued through the preoperative period and during cardiac catheterization. Because prostaglandin can cause apnea, an individual skilled in neonatal intubation should be readily available.

Infants with less-severe right ventricular outflow tract obstruction who are stable and awaiting surgical intervention require careful observation. Acyanotic patients can fairly quickly progress to having cyanotic episodes. Prevention or prompt treatment of dehydration is important to avoid hemoconcentration and possible thrombotic episodes. Oral propranolol (0.5-1 mg/kg every 6 hr) had been used in the past to decrease the frequency and severity of hypercyanotic spells, but with the excellent surgical results available today, surgical treatment is now indicated as soon as spells begin.

Infants with symptoms and severe cyanosis in the 1st mo of life usually have marked obstruction of the right ventricular outflow tract. Two options are available in these infants. The first is corrective open heart surgery performed in early infancy and even in the newborn period in critically ill infants. This approach has widespread acceptance today with excellent short- and long-term results and has supplanted palliative shunts (see later) for most cases. Early total repair carries the theoretical advantage that early physiologic correction allows for improved growth of the branch pulmonary arteries. In infants with less-severe cyanosis who can be maintained with good growth and absence of hypercyanotic spells, primary repair is performed electively at between 4 and 6 mo of age.

Corrective surgical therapy consists of relief of the right ventricular outflow tract obstruction by resecting obstructive muscle bundles and by patch closure of the VSD. If the pulmonary valve is stenotic, as it usually is, a valvotomy is performed. If the pulmonary valve annulus is too small or the valve is extremely thickened, a valvectomy may be performed, the pulmonary valve annulus split open, and a transannular patch placed across the pulmonary valve ring. The surgical risk of total correction in major centers is <5%. A right ventriculotomy was once the standard approach; a transatrial–transpulmonary approach is routinely performed to reduce the long-term risks of a large right ventriculotomy. In patients in whom repair has been delayed to childhood, increased bleeding in the immediate postoperative period may be a complicating factor because of their extreme polycythemia.

The second option, more common in previous years, is a palliative systemic-to-pulmonary artery shunt (**Blalock-Taussig shunt**) performed to augment pulmonary artery blood flow. The rationale for this surgery, previously the only option for these patients, is to augment pulmonary blood flow to decrease the amount of hypoxia and improve linear growth, as well as augment growth of the branch pulmonary arteries. The modified Blalock-Taussig shunt is currently the most common aortopulmonary shunt procedure and consists of a Gore-Tex conduit anastomosed side to side from the subclavian artery to the homolateral branch of the pulmonary artery (Fig. 430-5). Sometimes the shunt is brought directly from the ascending aorta to the main pulmonary artery; in this case, it is called a central shunt. Postoperative complications after a Blalock-Taussig shunt include chylothorax, diaphragmatic paralysis, and Horner syndrome. Postoperative pulmonary overcirculation leading to symptoms of cardiac failure may be caused by too large a shunt; Chapter 442 describes its treatment. Vascular problems other than a diminished radial pulse and occasional long-term arm length discrepancy are rarely seen in the upper extremity supplied by the subclavian artery used for the anastomosis.

After a successful shunt procedure, cyanosis diminishes. The development of a continuous murmur over the lung fields after the operation indicates a functioning anastomosis. A good continuous shunt murmur may not be heard until several days after surgery. The duration of symptomatic relief is variable. As the child grows, more pulmonary blood flow is needed and the shunt eventually becomes inadequate. When increasing cyanosis develops rapidly, thrombosis of the shunt should be suspected, often requiring emergent surgery.

Currently, Blalock-Taussig shunts are usually reserved for patients with comorbidities, such as other major congenital anomalies or

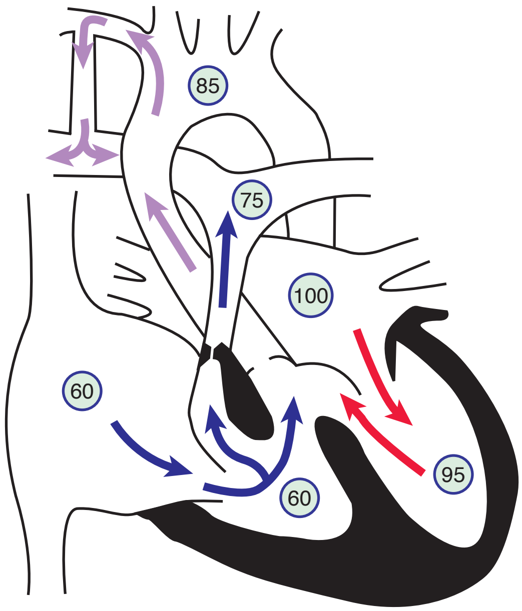

Figure 430-5 Physiology of a Blalock-Taussig shunt in a patient with tetralogy of Fallot. *Circled numbers* represent oxygen saturation values. The intracardiac shunting pattern is as described for Figure 430-1. Blood shunting left to right across the shunt from the right subclavian artery to the right pulmonary artery increases total pulmonary blood flow and results in a higher oxygen saturation than would exist without the shunt (see Fig. 430-1).

prematurity, that would make full repair a higher risk option. However, many surgeons still recommend full repair in these situations, being preferable to the combined risks of a staged procedure, and successful repairs have been done even in small premature infants.

PROGNOSIS

After successful total correction, patients are generally asymptomatic and are able to lead unrestricted lives. Uncommon immediate postoperative problems include right ventricular failure, transient heart block, residual VSD with left-to-right shunting, and myocardial infarction from interruption of an aberrant coronary artery. Postoperative heart failure (particularly in patients with a large transannular outflow patch) may require anticongestive therapy. The long-term effects of isolated, surgically induced pulmonary valvular insufficiency are still being defined as more patients with repaired tetralogy of Fallot reach middle age, but insufficiency is generally well-tolerated through adolescence. Many patients after tetralogy repair and all of those with transannular patch repairs have a to-and-fro murmur at the left sternal border, usually indicative of mild outflow obstruction and mild to moderate pulmonary insufficiency. Patients with more marked pulmonary valve insufficiency may also have moderate to more severe degrees of right ventricular enlargement and may develop tricuspid regurgitation as the tricuspid valve annulus dilates. These patients will develop a holosystolic murmur at the lower left sternal border. Patients with a severe residual gradient across the right ventricular outflow tract may require reoperation, but mild to moderate degrees of residual obstruction usually do not require reintervention.

Follow-up of patients 5-20 yr after surgery indicates that the marked improvement in symptoms is generally maintained. Asymptomatic patients nonetheless have lower than normal exercise capacity, maximal heart rate, and cardiac output. These abnormal findings are more common in patients who underwent placement of a transannular outflow tract patch and may be less frequent when surgery is performed at an early age. As these children move into adolescence and adulthood, some (more commonly those with transannular patches) will develop right ventricular dilation as a result of severe pulmonary

regurgitation. After reaching adulthood, careful lifelong follow-up by a specialist in adult congenital heart disease is important. Serial echocardiography and the more quantitative magnetic resonance angiography are valuable tools for assessing the degree of right ventricular dilation, the presence of right ventricular dysfunction, and for quantifying the regurgitant fraction. Valve replacement is indicated for those patients with increasing right ventricular dilation and tricuspid regurgitation. For patients requiring valve replacement, new nonsurgical options are being developed. Stent valves, which can be delivered in the cardiac catheterization lab, have been used successfully in many patients with repaired tetralogy of Fallot. These are being used predominantly in patients who have previously had a homograft or other artificial conduit placed between the right ventricular and pulmonary arteries.

Conduction disturbances can occur after surgery. The atrioventricular node and the bundle of His and its divisions are in close proximity to the VSD and may be injured during surgery; however, permanent complete heart block after tetralogy repair is rare. When present, it should be treated by placement of a permanently implanted pacemaker. Even transient complete heart block in the immediate postoperative period is rare; it may be associated with an increased incidence of late-onset complete heart block and sudden death. In contrast, right bundle-branch block is quite common on the postoperative electrocardiogram. The duration of the QRS interval has been shown to predict both the presence of residual hemodynamic derangement and the long-term risk of arrhythmia and sudden death. Research is ongoing to determine the effectiveness of biventricular pacing (in which a pacemaker is used to resynchronize the activation of the right and left ventricles) in improving hemodynamics in those patients with long ventricular conduction delays.

A number of children have premature ventricular beats after repair of the tetralogy of Fallot. These beats are of concern in patients with residual hemodynamic abnormalities; 24 hr electrocardiographic (Holter) monitoring studies should be performed to be certain that occult short episodes of ventricular tachycardia are not occurring. Exercise studies may be useful in provoking cardiac arrhythmias that are not apparent at rest. In the presence of complex ventricular arrhythmias or severe residual hemodynamic abnormalities, prophylactic antiarrhythmic therapy, catheter ablation, or implantation of an implantable defibrillator is warranted. Rerepair is indicated if significant residual right ventricular outflow obstruction or severe pulmonary insufficiency is present because arrhythmias may improve after hemodynamics is restored to a more normal level.

430.2 Tetralogy of Fallot with Pulmonary Atresia

Daniel Bernstein

PATHOPHYSIOLOGY

Tetralogy of a Fallot with pulmonary atresia is the most extreme form of the tetralogy of Fallot. The pulmonary valve is atretic (absent), and the pulmonary trunk may be hypoplastic or atretic as well. The entire right ventricular output is ejected into the aorta. Pulmonary blood flow is then dependent on collateral vessels or MAPCAs, or, rarely, on a PDA. The ultimate prognosis depends on the degree of development of the branch pulmonary arteries, which needs to be assessed by cardiac catheterization. If the pulmonary arteries are severely hypoplastic and fail to grow after palliative shunt procedures, heart-lung transplantation may be the only therapy (see Chapter 443.2). Pulmonary atresia with VSD is also associated with the 22q11.2 deletion and DiGeorge syndrome. The association of severe **tracheomalacia** or **bronchomalacia** with these severe forms of tetralogy/pulmonary atresia may complicate postoperative recovery.

CLINICAL MANIFESTATIONS

Patients with pulmonary atresia and VSD have findings similar to those in patients with severe tetralogy of Fallot. Cyanosis usually appears within the 1st few hr or days after birth; however, the prominent systolic murmur associated with the tetralogy is usually absent. The 1st heart sound may be followed by an ejection click caused by the enlarged aortic root, the 2nd heart sound is single and loud, and continuous murmurs of collateral flow may be heard over the entire precordium, both anteriorly and posteriorly. Most patients are moderately cyanotic and are initially stabilized with a prostaglandin E_1 infusion pending cardiac catheterization or CT scan to further delineate the anatomy. Patients with several large MAPCAs may be less cyanotic and, once the diagnosis is confirmed, can be taken off prostaglandin while awaiting palliative surgical intervention. Some patients may even develop symptoms of heart failure caused by increased pulmonary blood flow via these collateral vessels.

DIAGNOSIS

The chest roentgenogram demonstrates a varying heart size, depending on the amount of pulmonary blood flow, a concavity at the position of the pulmonary arterial segment, and often the reticular pattern of bronchial collateral flow. The electrocardiogram shows right ventricular hypertrophy. The echocardiogram identifies aortic override, a thick right ventricular wall, and atresia of the pulmonary valve. Pulsed and color Doppler echocardiographic studies show an absence of forward flow through the pulmonary valve, with pulmonary blood flow being supplied by MAPCAs, which can usually be seen arising from the descending aorta. At cardiac catheterization, right ventriculography reveals a large aorta, opacified immediately by passage of contrast medium through the VSD, but with no dye entering the lungs through the right ventricular outflow tract. Careful delineation of the native pulmonary arteries, if present, to determine whether they are continuous or discontinuous and whether they arborize to all lung segments is important in planning surgical repair. The location and arborization of all MAPCAs and the presence of any localized stenosis are determined by selective contrast injection. CT angiography has recently been utilized to assist in mapping the extent of MAPCA arborization.

TREATMENT

The surgical procedure of choice depends on whether the main pulmonary artery segment is present and, if so, on the size and branching pattern of the branch pulmonary arteries. If these arteries are well developed, a one-stage surgical repair with a homograft conduit between the right ventricle and pulmonary arteries and closure of the VSD is feasible. If the pulmonary arteries are hypoplastic, extensive reconstruction may be required. This usually involves several staged surgical procedures. If the native pulmonary artery is present but small, a connection made between the aorta and the hypoplastic native pulmonary artery (aortopulmonary window) in the newborn period induces growth. At 3-4 mo of age, the multiple MAPCAs are gathered together (unifocalization procedure) and eventually incorporated into the final repair along with the native pulmonary arteries. This may be accomplished through successive lateral thoracotomies, or through a single midline sternotomy if the anatomy is more favorable.

To be a candidate for full repair, the pulmonary arteries must be of adequate size to accept the full volume of right ventricular output. Complete repair includes closure of the VSD and placement of a homograft conduit from the right ventricle to the pulmonary artery. At the time of reparative surgery, previous shunts are taken down. Because of patient growth as well as homograft narrowing due to proliferation of intimal tissue and calcification, replacement of the homograft conduit replacement is usually required in later life, and multiple replacements may be needed. Many of these patients are candidates for placement of a transcatheter stent valve in the pulmonary position. Patients with obstruction of the very distal branches of the pulmonary arteries may undergo repeat surgical procedures or transcatheter balloon dilation

430.3 Pulmonary Atresia with Intact Ventricular Septum

Daniel Bernstein

PATHOPHYSIOLOGY

In pulmonary atresia with an intact ventricular septum, the pulmonary valve leaflets are completely fused to form a membrane and the right ventricular outflow tract is atretic. Because no VSD is present, no egress of blood from the right ventricle can occur. Any blood that enters the right ventricle will regurgitate back across the tricuspid valve into the right atrium. Right atrial pressure increases, and blood shunts via the foramen ovale into the left atrium, where it mixes with pulmonary venous blood and enters the left ventricle (Fig. 430-6). The combined left and right ventricular output is pumped solely by the left ventricle into the aorta. In a newborn with pulmonary atresia, the only source of pulmonary blood flow occurs via a **PDA.** The right ventricle and tricuspid valve are usually hypoplastic, although the degree of hypoplasia varies considerably. Patients who have a small right ventricular cavity also tend to be those with the smallest tricuspid valve annulus, which limits right ventricular inflow. Patients with pulmonary atresia and intact ventricular septum may have **coronary sinusoidal channels** within the right ventricular wall that communicate directly with the coronary arterial circulation. The high right ventricular pressure results in desaturated blood flowing retrograde via these channels into the coronary arteries. Sometimes there are also stenoses of the coronary arteries proximal to where the sinusoids enter, so that distal coronary artery flow is dependent on flow from the right ventricle (known as *right ventricle–dependent coronary circulation*). The prognosis in patients with these sinusoids and proximal stenosis of the coronary arteries is more guarded than in those patients without sinusoids or with sinusoids but no coronary stenoses. Rarely, the proximal coronary artery may be totally absent.

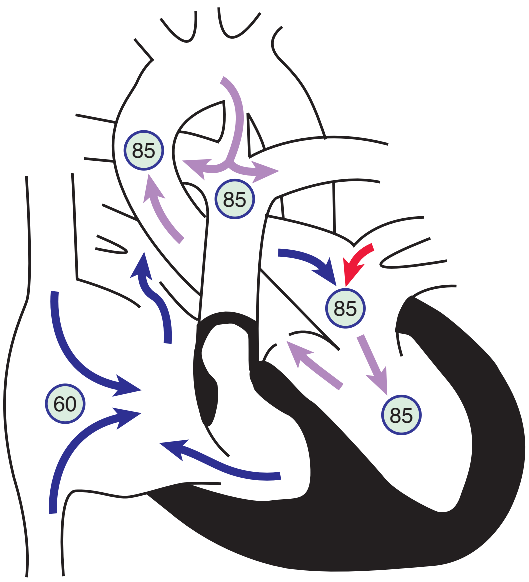

Figure 430-6 Physiology of pulmonary atresia with an intact ventricular septum. *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. A small amount of the blood entering the right atrium may cross the tricuspid valve, which is often stenotic as well. The right ventricular cavity is hypertrophied and may be hypoplastic. No outlet from the right ventricle exists because of the atretic pulmonary valve; thus, any blood entering the right ventricle returns to the right atrium via tricuspid regurgitation. Most of the desaturated blood shunts right to left via the foramen ovale into the left atrium, where it mixes with fully saturated blood returning from the lungs. The only source of pulmonary blood flow is via the patent ductus arteriosus. Aortic and pulmonary arterial oxygen saturation will be identical (definition of a total mixing lesion).

CLINICAL MANIFESTATIONS

As the ductus arteriosus closes in the 1st hr and days of life, infants with pulmonary atresia and an intact ventricular septum become markedly cyanotic because their only source of pulmonary blood flow is removed. Untreated, most patients die within the 1st wk of life. Physical examination reveals severe cyanosis and respiratory distress. The 2nd heart sound, representing only aortic closure, is single and loud. Often, no murmurs are audible; sometimes a systolic or continuous murmur can be heard secondary to ductal blood flow. A harsh holosystolic murmur may be heard at the lower left sternal border if there is significant tricuspid regurgitation.

DIAGNOSIS

The electrocardiogram shows a frontal QRS axis between 0 and +90 degrees, the amount of leftward shift reflecting the degree of hypoplasia of the right ventricle. Tall, spiked P waves indicate right atrial enlargement. QRS voltages are consistent with left ventricular dominance or hypertrophy; right ventricular forces are decreased in proportion to the decreased size of the right ventricular cavity. Most patients with small right ventricles have decreased right ventricular forces, but, occasionally, patients with larger, thickened right ventricular cavities may have evidence of right ventricular hypertrophy. The chest roentgenogram shows decreased pulmonary vascularity, the degree depending on the size of the branch pulmonary arteries and the patency of the ductus. Unlike in patients with pulmonary atresia and tetralogy of Fallot, the presence of major collateral vessels (MAPCAs) is rare.

The 2-dimensional echocardiogram is useful in estimating right ventricular dimensions and the size of the tricuspid valve annulus, which have been shown to be of prognostic value. Echocardiography can often suggest the presence of sinusoidal channels but cannot be used to evaluate coronary stenoses. Thus, cardiac catheterization is necessary for complete evaluation. Pressure measurements reveal right atrial and right ventricular hypertension. Ventriculography demonstrates the size of the right ventricular cavity, the atretic right ventricular outflow tract, the degree of tricuspid regurgitation, and the presence or absence of intramyocardial sinusoids filling the coronary vessels. Aortography shows filling of the pulmonary arteries via the PDA and is helpful in determining the size and branching patterns of the pulmonary arterial bed. An aortogram, or if necessary selective coronary angiography is performed to evaluate for the presence of proximal coronary artery stenosis (right ventricular dependent coronary circulation).

TREATMENT

Infusion of prostaglandin E_1 (0.01-0.20 μg/kg/min) is usually effective in keeping the ductus arteriosus open before intervention, thus reducing hypoxemia and acidemia before surgery. The choice of surgical procedure depends on whether there is an RV dependent coronary circulation and on the size of the right ventricular cavity. In patients with only mild to moderate right ventricular hypoplasia without sinusoids, or in patients with sinusoids but no evidence of coronary stenoses, a surgical pulmonary valvotomy is carried out to relieve outflow obstruction. Often, the right ventricular outflow tract is widened with a patch. To preserve adequate pulmonary blood flow, an aortopulmonary shunt may also be performed during the same procedure. An alternative approach uses interventional catheterization, in which the imperforate pulmonary valve is first punctured either with a wire or a radiofrequency ablation catheter, followed by a balloon valvuloplasty.

If this course is taken, it may take days to weeks before the right ventricular muscle regresses enough for the patient to be weaned from prostaglandin, and many of these patients will still require surgical intervention. The aim of surgery or interventional catheterization is to encourage growth of the right ventricular chamber by allowing some forward flow through the pulmonary valve while using the shunt to ensure adequate pulmonary blood flow. Later, if the tricuspid valve annulus and right ventricular chamber grow to adequate size, the shunt is taken down and any remaining atrial level shunt can be closed. If the right ventricular chamber remains too small for use as a pulmonary ventricle, then the patient is treated as a single ventricle circulation, with a **Glenn procedure** followed by a modified **Fontan procedure** (see Chapter 430.4), allowing blood to bypass the hypoplastic right ventricle by flowing to the pulmonary arteries directly from the venae cavae. When coronary artery stenoses are present and retrograde coronary perfusion occurs from the right ventricle via myocardial sinusoids, the prognosis is more guarded because of a higher risk of arrhythmias, coronary ischemia, and sudden death. It is important for these patients not to try to open the right ventricular outflow tract, as dropping the right ventricular pressure will reduce coronary perfusion, leading to ischemia. These patients are usually treated with an aortopulmonary shunt, followed by the Glenn and Fontan procedure. Although at higher risk than those without coronary stenoses, recent reports show good success with this approach. A small number of these infants, especially those with total atresia of a proximal coronary artery, are referred instead for heart transplantation.

Bibliography is available at Expert Consult.

430.4 Tricuspid Atresia

Daniel Bernstein

PATHOPHYSIOLOGY

In tricuspid atresia, no outlet from the right atrium to the right ventricle is present; the entire systemic venous return leaves the right atrium and enters the left side of the heart by means of the foramen ovale or, most often, through an atrial septal defect (Fig. 430-7). The physiology of the circulation and the clinical presentation will depend on the presence of other congenital heart defects, most notably on whether the great vessels are normally related or are transposed (aorta arising from the right ventricle, pulmonary artery from the left ventricle). In patients with normally related great vessels, left ventricular blood supplies the systemic circulation via the aorta. Blood also usually flows into the right ventricle via a VSD (if the ventricular septum is intact, the right ventricle will be completely hypoplastic and pulmonary atresia will be present [see Chapter 430.3]). *Pulmonary blood flow (and thus the degree of cyanosis) depends on the size of the VSD and the presence and severity of any associated pulmonic stenosis.* Pulmonary blood flow may be augmented by or be totally dependent on a PDA. The inflow portion of the right ventricle is always missing in these patients, but the outflow portion is of variable size. The clinical presentation of patients with tricuspid atresia and normally related great vessels will depend on the degree of pulmonary obstruction. Patients with at least moderate degrees of pulmonary stenosis are recognized in the early days or weeks of life by decreased pulmonary blood flow and cyanosis. Alternatively, in those with a large VSD and minimal or no right ventricular outflow obstruction, pulmonary blood flow may be high; these patients have only mild cyanosis and present with signs of pulmonary overcirculation and heart failure.

In patients with tricuspid atresia and transposition of the great arteries, left ventricular blood flows directly into the pulmonary artery, whereas systemic blood must traverse the VSD and right ventricle to reach the aorta. In these patients, pulmonary blood flow is usually massively increased and heart failure develops early. If the VSD is restrictive, aortic blood flow may be compromised. Coarctation of the aorta is not uncommon in this setting.

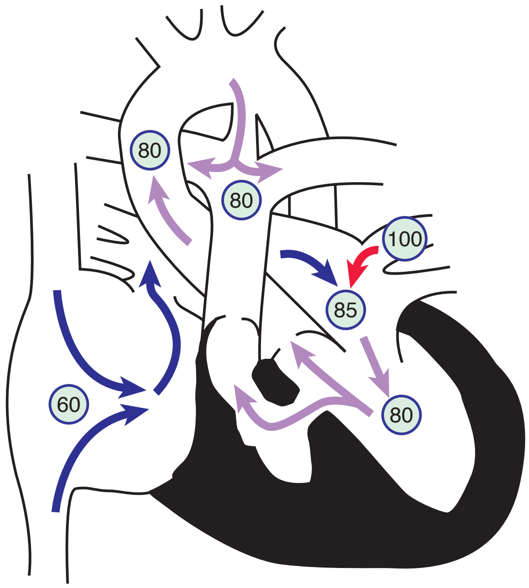

Figure 430-7 **Physiology of tricuspid atresia with normally related great vessels.** *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. The tricuspid valve is nonpatent, and the right ventricle may manifest varying degrees of hypoplasia. The only outlet from the right atrium involves shunting right to left across an atrial septal defect or patent foramen ovale to the left atrium. There, desaturated blood mixes with saturated pulmonary venous return. Blood enters the left ventricle and is ejected either through the aorta or via a ventricular septal defect (VSD) into the right ventricle. In this example, some pulmonary blood flow is derived from the right ventricle, the rest from a patent ductus arteriosus (PDA). In patients with tricuspid atresia, the PDA may close or the VSD may grow smaller and result in a marked decrease in systemic oxygen saturation.

CLINICAL MANIFESTATIONS

Some degree of cyanosis is usually evident at birth, with the extent depending on the degree of limitation to pulmonary blood flow (as noted above). An increased left ventricular impulse may be noted, in contrast to most other causes of cyanotic heart disease, in which an increased right ventricular impulse is usually present. The majority of patients have holosystolic murmurs audible along the left sternal border; the 2nd heart sound is usually single. Pulses in the lower extremities may be weak or absent in the presence of transposition with coarctation of the aorta. Patients with tricuspid atresia are at risk for spontaneous narrowing or even closure of the VSD, which can occasionally occur rapidly and lead to a marked increase in cyanosis.

DIAGNOSIS

Radiologic studies show either pulmonary under circulation (usually in patients with normally related great vessels) or over circulation (usually in patients with transposed great vessels). Left axis deviation and left ventricular hypertrophy are generally noted on the electrocardiogram (except in those patients with transposition of the great arteries), and these features distinguish tricuspid atresia from most other cyanotic heart lesions. Thus the combination of cyanosis and left axis deviation on the electrocardiogram is highly suggestive of tricuspid atresia. In the right precordial leads, the normally prominent R wave is replaced by an rS complex. The left precordial leads show a qR complex, followed by a normal, flat, biphasic, or inverted T wave. RV_6 is normal or tall, and SV_1 is generally deep. The P waves are usually biphasic, with the initial component tall and spiked in lead II. Two-dimensional echocardiography reveals the presence of a fibromuscular membrane in place of a tricuspid valve, a variably small right ventricle, VSD, and the large left ventricle (Fig. 430-8). The relationship of the great vessels (normal or transposed) can be determined. The degree of

obstruction at the level of the VSD or at the right ventricular outflow tract can be determined by Doppler examination. Blood flow through a patent ductus can be evaluated by color flow and pulsed Doppler.

Cardiac catheterization, indicated usually only if questions remain after echocardiography, shows normal or slightly elevated right atrial pressure with a prominent *a* wave. If the right ventricle is entered through the VSD, the pressure may be lower than on the left if the VSD is restrictive in size. Right atrial angiography shows immediate opacification of the left atrium from the right atrium followed by left ventricular filling and visualization of the aorta. Absence of direct flow to the right ventricle results in an angiographic filling defect between the right atrium and the left ventricle.

TREATMENT

Management of patients with tricuspid atresia depends on the adequacy of pulmonary blood flow. Severely cyanotic neonates should be maintained on an intravenous infusion of prostaglandin E_1 (0.01-0.20 µg/kg/min) until a surgical aortopulmonary shunt procedure can be performed to increase pulmonary blood flow. The Blalock-Taussig procedure (see Chapter 430.1) or a variation is the preferred anastomosis. Rare patients with restrictive atrial-level communications also benefit from a Rashkind balloon atrial septostomy (see Chapter 431.2) or surgical septectomy.

Infants with increased pulmonary blood flow because of an unobstructed pulmonary outflow tract (more often patients with aortopulmonary transposition) may require pulmonary arterial banding to decrease the symptoms of heart failure and protect the pulmonary bed from the development of pulmonary vascular disease. Infants with just adequate pulmonary blood flow who are well balanced between cyanosis and pulmonary overcirculation can be watched closely for the development of increasing cyanosis, which may occur as the VSD begins to get smaller or the pulmonary outflow becomes narrower and is an indication for surgery.

The next stage of palliation for patients with tricuspid atresia involves the creation of an anastomosis between the superior vena cava and the pulmonary arteries (**bidirectional Glenn shunt;** Fig. 430-9*A*). This procedure is performed at usually between 3 and 6 mo of age. The benefit of the Glenn shunt is that it reduces the volume load on the left ventricle and may lessen the chance of left ventricular dysfunction developing later in life.

The **modified Fontan operation** is the preferred approach to later surgical management. It is usually performed between 1.5 and 3 yr of age, usually after the patient is ambulatory. Initially, this procedure was performed by anastomosing the right atrium or atrial appendage directly to the pulmonary artery. The most commonly used procedure today is a modification of the Fontan procedure, known as a *cavopulmonary isolation procedure,* which involves anastomosing the inferior vena cava to the pulmonary arteries, either via a baffle that runs along the lateral wall of the right atrium (lateral tunnel Fontan; see Fig. 430-9*B*) or via a homograft or Gore-Tex tube running outside the heart (external conduit Fontan). The advantage of these later approaches is that blood flows by a more direct route into the pulmonary arteries, thereby decreasing the possibility of right atrial dilation and markedly reducing the incidence of postoperative pleural effusions, which were

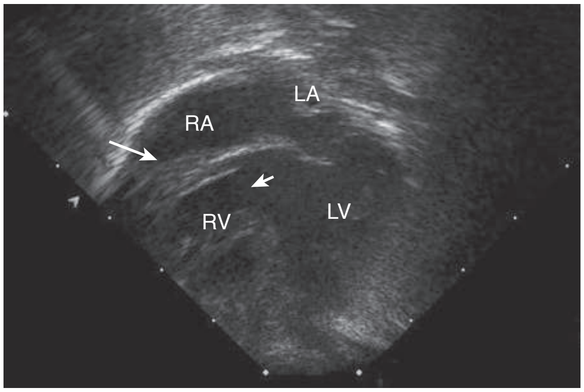

Figure 430-8 Echocardiogram demonstrating tricuspid atresia. The floor of the right atrium consists of a fibromuscular membrane *(large arrow)* instead of the normal tricuspid valve apparatus. The large secundum atrial septal defect can be seen between the right and left atria. The *small arrow* shows the ventricular septal defect. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

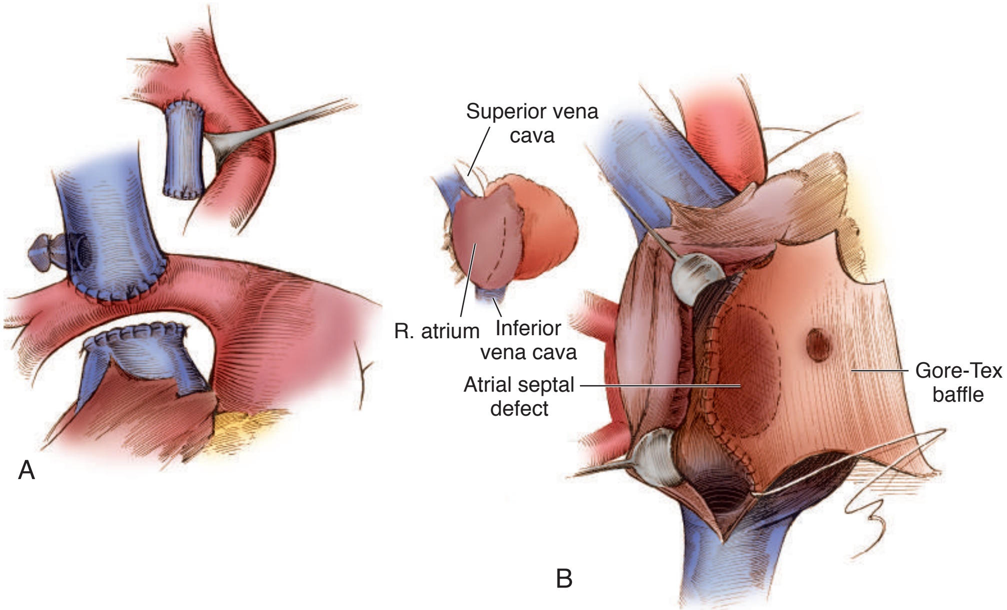

Figure 430-9 A, Bidirectional Glenn shunt showing the superior vena cava–right pulmonary anastomosis. **B,** A modified Fontan procedure (cavopulmonary isolation) is completed with placement of a baffle to convey inferior vena cava blood along the lateral wall of the right atrium to the superior vena cava orifice. A 4-mm fenestration is sometimes made on the medial aspect of the polytetrafluoroethylene baffle. *(From Castañeda AR, Jonas RA, Mayer JE Jr, et al: Single-ventricle tricuspid atresia. In* Cardiac surgery of the neonate and infant, *Philadelphia, 1994, WB Saunders.)*

common with the earlier method. In a completed Fontan repair, desaturated blood flows from both venae cavae directly into the pulmonary arteries. Oxygenated blood returns to the left atrium, enters the left ventricle, and is ejected into the systemic circulation. The volume load is completely removed from the left ventricle, and the right-to-left shunt is abolished. Because of the reliance on passive filling of the pulmonary circulation, the Fontan procedure is contraindicated in patients with elevated pulmonary vascular resistance, in those with pulmonary artery hypoplasia, and in patients with left ventricular dysfunction. The patient must also not have significant mitral insufficiency. Patients who are not in normal sinus rhythm are at increased risk and if a pacemaker is required in these patients, dual chamber pacing is the preferred approach.

Postoperative problems after the Fontan procedure include marked elevation of systemic venous pressure, fluid retention, and pleural or pericardial effusions. In the past, pleural effusions were a problem in 30-40% of patients using the standard Fontan procedure, but the cavopulmonary isolation procedure now in use reduces this risk to approximately 5%. Some centers use a fenestration at the time of the Fontan, consisting of a small communication between the inferior vena cava and the pulmonary artery conduit and the left atrium. This serves as a "pop-off" during early postoperative recovery and may hasten hospital discharge. The fenestration will result in some amount of right-to-left shunting, and is therefore usually closed with a catheter closure device after the immediate postoperative period.

Late complications of the Fontan procedure include baffle obstruction causing superior or inferior vena cava syndrome, vena cava or pulmonary artery thromboembolism, protein-losing enteropathy, plastic bronchitis, supraventricular arrhythmias (atrial flutter, paroxysmal atrial tachycardia), and hepatic cirrhosis (and possibly hepatic carcinoma) as a result of persistently elevated central venous pressures. Oral budesonide or sildenafil has been used with varying success to treat protein losing enteropathy associated with the Fontan procedure. Left ventricular dysfunction may be a late occurrence, usually not until adolescence or young adulthood. Heart transplantation is a successful treatment option for pediatric patients with "failed" Fontan circuits but is a somewhat riskier procedure in adults.

Bibliography is available at Expert Consult.

430.5 Double-Outlet Right Ventricle

Daniel Bernstein

Double-outlet right ventricle (DORV) is characterized when both the aorta and pulmonary artery arise from the right ventricle. The outlet from the left ventricle is through VSD into the right ventricle. Normally, the aortic and mitral valves are in fibrous continuity; in DORV, the aortic and mitral valves are separated by a smooth muscular conus, similar to that seen under the normal pulmonary valve. In DORV, the great arteries may be normally related, with the aorta closer to the VSD, or malposed, with the pulmonary artery closer to the VSD. The great artery closest to the VSD may override the defect by a variable amount but is at least 50% committed to the right ventricle. When the VSD is subaortic, the defect may be viewed as part of a continuum with the tetralogy of Fallot, and the physiology as well as the history, physical examination, electrocardiogram, and roentgenograms are depending on the degree of pulmonary stenosis, similar to the situation in tetralogy of Fallot (see Chapter 430.1). If the VSD is subpulmonic, there may be subvalvar, valvar, or supravalvar aortic stenosis, and coarctation is a possibility as well. This is known as the **Taussig-Bing malformation.** The clinical presentation of these patients will be dependent on the degree of aortic obstruction, but because the pulmonary artery is usually wide open, the presentation will usually include some degree of pulmonary overcirculation and heart failure. If the aortic obstruction is severe or there is a coarctation, poor pulses, hypoperfusion, and cardiovascular collapse are possible presenting signs.

The 2-dimensional echocardiogram demonstrates both great vessels arising from the right ventricle and mitral-aortic valve discontinuity. The relationships between the aorta and pulmonary artery to the VSD can be delineated, and the presence of either pulmonary obstruction or aortic obstruction can be evaluated. Cardiac catheterization is not necessarily required if the echocardiogram is straightforward. Angiography will show that the aortic and pulmonary valves lie in the same horizontal plane and that both arise predominantly or exclusively from the right ventricle.

Surgical correction depends on the relationship of the great vessels to the VSD. If the VSD is subaortic, the repair may be similar to that used for tetralogy of Fallot, or consist of creating an intraventricular tunnel so that the left ventricle ejects blood through the VSD, into the tunnel, and into the aorta. The pulmonary obstruction is relieved either with an outflow patch or with a right ventricular to pulmonary artery homograft conduit **(Rastelli operation).** If the VSD is subpulmonic, the great vessels can be switched (see Chapter 430.6) and the Rastelli operation performed. However, if there is substantial aortic obstruction, or if 1 of the ventricles is hypoplastic, then a Norwood-style single-ventricle repair may be necessary (see Chapter 431.10). In small infants, palliation with an aortopulmonary shunt provides symptomatic improvement and allows for adequate growth before corrective surgery is performed.

430.6 Transposition of the Great Arteries with Ventricular Septal Defect and Pulmonary Stenosis

Daniel Bernstein

This combination of anomalies may mimic tetralogy of Fallot in its clinical features (see Chapter 430.1). However, because of the transposed great vessels, the site of obstruction is in the left as opposed to the right ventricle. The obstruction can be either valvular or subvalvular; the latter type may be dynamic, related to the interventricular septum or atrioventricular valve tissue, or acquired, as in patients with transposition and VSD after pulmonary arterial banding.

The age at which clinical manifestations initially appear varies from soon after birth to later infancy, depending on the degree of pulmonic stenosis. Clinical findings include cyanosis, decreased exercise tolerance, and poor physical development, similar to those described for tetralogy of Fallot; the heart is usually more enlarged. The pulmonary vasculature as seen on the roentgenogram is dependent on the degree of pulmonary obstruction. The electrocardiogram usually shows right axis deviation, right and left ventricular hypertrophy, and sometimes tall, spiked P waves. Echocardiography confirms the diagnosis and is useful in sequential evaluation of the degree and progression of the left ventricular outflow tract obstruction. Cardiac catheterization, if necessary, shows that pulmonary arterial pressure is low and that oxygen saturation in the pulmonary artery exceeds that in the aorta. Selective right and left ventriculography demonstrates the origin of the aorta from the right ventricle, the origin of the pulmonary artery from the left ventricle, the VSD, and the site and severity of the pulmonary stenosis.

An infusion of prostaglandin E_1 (0.01-0.20 μg/kg/min) should be started in neonates who present with cyanosis. When necessary, balloon atrial septostomy is performed to improve atrial-level mixing and to decompress the left atrium (see Chapter 431.2). Cyanotic infants may be palliated with an aortopulmonary shunt (see Chapter 430.1) followed by a Rastelli operation when older as the preferred corrective procedure. The Rastelli procedure achieves physiologic and anatomic correction by (1) closure of the VSD using an interventricular tunnel so that left ventricular blood flow is directed to the aorta, and (2) connection of the right ventricle to the pulmonary artery via an extracardiac homograft conduit between the right ventricle and the distal pulmonary artery (Fig. 430-10). These conduits will eventually become stenotic or functionally restrictive with growth of the patient and require replacement. Patients with milder degrees of pulmonary

stenosis amenable to simple valvotomy may be able to undergo complete correction with an arterial switch procedure (see Chapter 431.2) and closure of the VSD. Surgical correction by the Mustard operation (see Chapter 431.2) with simultaneous closure of the VSD and relief of left ventricular outflow obstruction may be an alternative when the position of the VSD is not suitable for a Rastelli operation; however, this procedure leaves the right ventricle as the systemic pumping chamber and has fallen out of favor.

430.7 Ebstein Anomaly of the Tricuspid Valve

Daniel Bernstein

PATHOPHYSIOLOGY

Ebstein anomaly consists of downward displacement of an abnormal tricuspid valve into the right ventricle. The defect arises from failure of the normal process by which the tricuspid valve is separated from the right ventricular myocardium (see Chapter 420). The anterior cusp of the valve retains some attachment to the valve ring, but the other leaflets are adherent to the wall of the right ventricle. The right ventricle is thus divided into 2 parts by the abnormal tricuspid valve: the first, a thin-walled "atrialized" portion, is continuous with the cavity of the right atrium; the second, often smaller portion consists of normal ventricular myocardium. The right atrium is enlarged as a result of tricuspid valve regurgitation, although the degree is extremely variable. In more severe forms of Ebstein anomaly, the effective output from the right side of the heart is decreased because of a combination of the poorly functioning small right ventricle, tricuspid valve regurgitation, and obstruction of the right ventricular outflow tract produced by the large, sail-like, anterior tricuspid valve leaflet. In newborns, right ventricular function may be so compromised that it is unable to generate enough force to open the pulmonary valve in systole, thus producing "functional" pulmonary atresia. Some infants have true anatomic pulmonary atresia. The increased volume of right atrial blood shunts through the foramen ovale (or through an associated atrial septal defect) to the left atrium and produces cyanosis (Fig. 430-11).

CLINICAL MANIFESTATIONS

The severity of symptoms and the degree of cyanosis are highly variable and depend on the extent of displacement of the tricuspid valve and the severity of right ventricular outflow tract obstruction. In many patients, symptoms are mild and may be delayed until the teenage years or young adult life; the patient may initially have fatigue or palpitations as a result of cardiac dysrhythmias. The atrial right-to-left shunt is responsible for cyanosis and polycythemia. Jugular venous pulsations, a index of central venous pressure, may be normal or increased in those with tricuspid insufficiency. On palpation, the precordium is quiet. A holosystolic murmur caused by tricuspid regurgitation is audible over most of the anterior left side of the chest. A gallop rhythm is common and often associated with multiple clicks at the lower left sternal border. A scratchy diastolic murmur may also be heard at the left sternal border. This murmur may mimic a pericardial friction rub.

Newborns with severe forms of Ebstein anomaly have marked cyanosis, massive cardiomegaly, and long holosystolic murmurs. Death may result from cardiac failure, hypoxemia, and pulmonary hypoplasia, the result of severe long-standing intrauterine right atrial enlargement. Spontaneous improvement may occur in some neonates as pulmonary vascular resistance falls and improves the ability of the right ventricle to provide pulmonary blood flow. The majority are

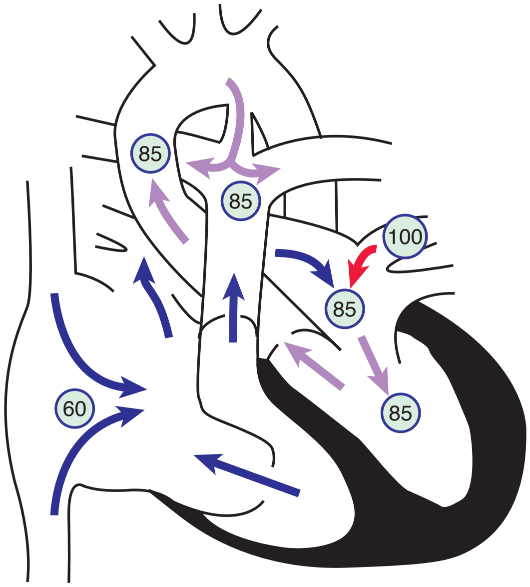

Figure 430-11 Physiology of Ebstein anomaly of the tricuspid valve. *Circled numbers* represent oxygen saturation values. Inferior displacement of the tricuspid valve leaflets into the right ventricle has resulted in a thin-walled, low-pressure "atrialized" segment of right ventricle. The tricuspid valve is grossly insufficient *(clear arrow)*. Right atrial blood flow is shunted right to left across an atrial septal defect or patent foramen ovale into the left atrium. Some blood may cross the right ventricular outflow tract and enter the pulmonary artery; however, in severe cases, the right ventricle may generate insufficient force to open the pulmonary valve, and "functional pulmonary atresia" results. In the left atrium, desaturated blood mixes with saturated pulmonary venous return. Blood enters the left ventricle and is ejected via the aorta. In this example, some pulmonary blood flow is derived from the right ventricle, the rest from a patent ductus arteriosus (PDA). Severe cyanosis will develop in neonates with a severe Ebstein anomaly when the PDA closes.

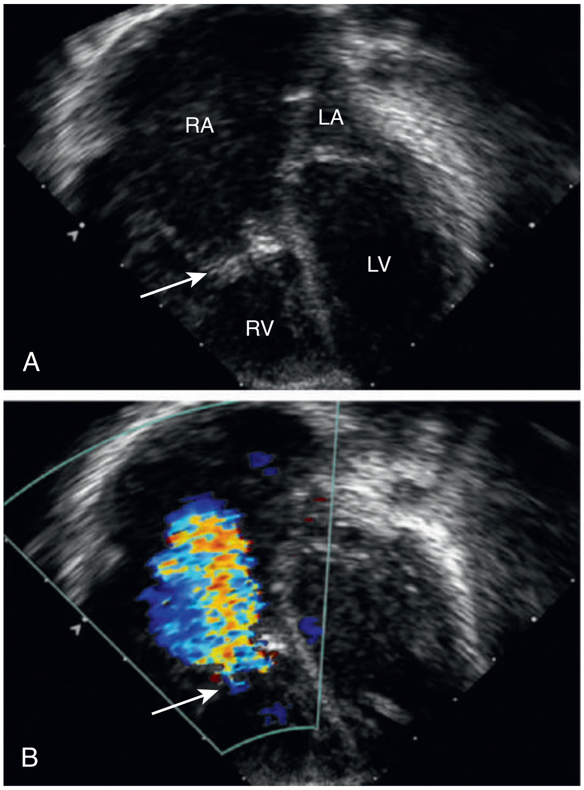

Figure 430-12 Echocardiographic demonstration of Ebstein anomaly of the tricuspid valve. **A,** Subcostal, 4-chamber, 2-dimensional view showing severe displacement of the tricuspid valve leaflets *(large arrow)* inferiorly into the right ventricle. The location of the tricuspid valve annulus is outlined by the 2 *arrowheads.* The portion of the right ventricle between the valve annulus and the valve leaflets is the "atrialized" component. **B,** Color Doppler examination showing severe regurgitation of the dysplastic tricuspid valve. Note that the regurgitant turbulent flow *(arrow)* begins halfway into the right ventricular chamber, at the location of the displaced valve leaflets. dependent on a PDA, and thus on a prostaglandin infusion, for pulmonary blood flow.

DIAGNOSIS

The electrocardiogram usually shows a right bundle-branch block without increased right precordial voltage, normal or tall and broad P waves, and a normal or prolonged P-R interval. **Wolff-Parkinson-White syndrome** (see Chapter 435) may be present and these patients may have episodes of supraventricular tachycardia. On radiographic examination, heart size varies from slightly enlarged to massive box-shaped cardiomegaly caused by enlargement of the right atrium. *In newborns with severe Ebstein anomaly, the heart may totally obscure the pulmonary fields.* Echocardiography is diagnostic and shows the degree of displacement of the tricuspid valve leaflets, a dilated right atrium, and any right ventricular outflow tract obstruction (Fig. 430-12). Pulsed and color Doppler examination demonstrates the degree of tricuspid regurgitation. In severe cases, the pulmonary valve may appear immobile and pulmonary blood flow may come solely from the ductus arteriosus. It may be difficult to distinguish true from functional pulmonary valve atresia. Cardiac catheterization, which is not usually necessary, confirms the presence of a large right atrium, an abnormal tricuspid valve, and any right-to-left shunt at the atrial level. The risk of arrhythmia is significant during catheterization and angiographic studies.

PROGNOSIS AND COMPLICATIONS

The prognosis in Ebstein anomaly is extremely variable and depends on the severity of the defect. The prognosis is more guarded for neonates or infants with intractable symptoms and cyanosis. Patients with milder degrees of Ebstein anomaly usually survive well into adult life. There is an association of a form of left ventricular cardiomyopathy, isolated left ventricular noncompaction, in 18% of patients with Ebstein anomaly, and the severity of the left ventricular dysfunction directly impacts the prognosis.

TREATMENT

Neonates with severe hypoxia who are prostaglandin dependent have been treated with an aortopulmonary shunt alone, by repair of the tricuspid valve, or by surgical patch closure of the tricuspid valve, atrial septectomy, and placement of an aortopulmonary shunt (with eventual single ventricle repair using the Fontan procedure [see Chapter 430.4]). Many infants with Ebstein anomaly who have undergone valve repair will still have enough regurgitation that a Glenn shunt is performed to reduce the volume load on the right ventricle (see Chapter 430.4). In older children with mild or moderate disease, control of supraventricular dysrhythmias is of primary importance; surgical treatment may not be necessary until adolescence or young adulthood. In patients with severe tricuspid regurgitation, repair or replacement of the abnormal tricuspid valve along with closure of the atrial septal defect is carried out. In some older patients, a bidirectional Glenn shunt is also performed, with the superior vena cava anastomosed to the pulmonary arteries. This procedure reduces the volume of blood that the dysfunctional right side of the heart has to pump, thus creating a "one-and-one-half ventricle repair."

Chapter 431

Cyanotic Congenital Heart Disease: Lesions Associated with Increased Pulmonary Blood Flow

431.1 D-Transposition of the Great Arteries

Daniel Bernstein

Transposition of the great vessels, a common cyanotic congenital anomaly, accounts for ≈5% of all congenital heart disease. In this anomaly, the systemic veins return normally to the right atrium and the pulmonary veins return to the left atrium. The connections between the atria and ventricles are also normal (atrioventricular concordance). The aorta arises from the right ventricle and the pulmonary artery from the left ventricle (Fig. 431-1). In normally related great vessels, the aorta is posterior and to the right of the pulmonary artery; in d-transposition of the great arteries (d-TGA), the aorta is anterior and to the right of the pulmonary artery (the *d* indicates a dextropositioned aorta, *transposition* indicates that it arises from the anterior right ventricle). Desaturated blood returning from the body to the right side of the heart goes inappropriately out the aorta and back to the body again, whereas oxygenated pulmonary venous blood returning to the left side of the heart is returned directly to the lungs. Thus, the systemic and pulmonary circulations exist as 2 parallel circuits. Survival in the immediate newborn period is provided by the foramen ovale and the ductus arteriosus, which permit some mixture of oxygenated and deoxygenated blood. Approximately 50% of patients with d-TGA also have a ventricular septal defect (VSD), which usually provides for better mixing. The clinical findings and hemodynamics vary in relation to the presence or absence of associated defects (e.g., VSD or pulmonary stenosis). d-TGA is more common in infants of diabetic mothers and in males (3:1). d-TGA, especially when accompanied by other cardiac defects such as pulmonic stenosis or right aortic arch, can be associated with deletion of chromosome 22q11.2 (DiGeorge syndrome [see Chapter 424]). Before the modern era of corrective or palliative surgery, mortality was >90% in the 1st yr of life.

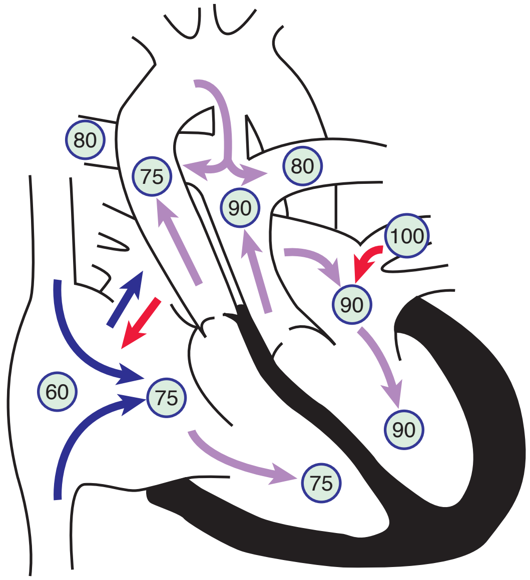

Figure 431-1 Physiology of d-transposition of the great arteries (d-TGA). *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Desaturated blood enters the right atrium, flows through the tricuspid valve into the right ventricle, and is ejected into the transposed aorta with resultant severe aortic desaturation. Fully saturated pulmonary venous blood flows into the left atrium, across the mitral valve into the left ventricle, and across the transposed pulmonary artery into the lungs. Pulmonary arterial oxygen saturation is thus increased. This lesion would not be compatible with life were it not for the ability of blood to shunt via 2 fetal pathways: the patent foramen ovale (PFO) and patent ductus arteriosus (PDA). Blood may shunt left to right or bidirectionally at the PFO. Because systemic vascular resistance tends to be higher than pulmonary vascular resistance, blood tends to shunt across the PDA mostly from the aorta to the pulmonary artery. As pulmonary resistance drops in the 1st few wk of life, pulmonary blood flow will gradually increase in patients with d-TGA.

431.2 D-Transposition of the Great Arteries with Intact Ventricular Septum

Daniel Bernstein

D-TGA with an intact ventricular septum is also referred to as simple TGA or isolated TGA. Before birth, oxygenation of the fetus is only slightly abnormal, but after birth, once the ductus arteriosus begins to close, the minimal mixing of systemic and pulmonary blood via the patent foramen ovale is usually insufficient and severe hypoxemia ensues, generally within the 1st few days of life.

CLINICAL MANIFESTATIONS

Cyanosis and tachypnea are most often recognized within the 1st hr or days of life. Untreated, the vast majority of these infants would not survive the neonatal period. Hypoxemia is usually moderate to severe, depending on the degree of atrial level shunting and whether the ductus is partially open or totally closed. This condition is a medical emergency, and only early diagnosis and appropriate intervention can avert the development of prolonged severe hypoxemia and acidosis, which lead to death. Physical findings, other than cyanosis, may be remarkably nonspecific. The precordial impulse may be normal, or a parasternal heave may be present. The 2nd heart sound is usually single and loud, although it may be split. Murmurs may be absent, or a soft systolic ejection murmur may be noted at the midleft sternal border.

DIAGNOSIS

The electrocardiogram is usually normal, showing the expected neonatal right-sided dominant pattern. Chest x-rays may show mild cardiomegaly, a narrow mediastinum (the classic "egg-shaped heart"), and normal to increased pulmonary blood flow. In the early newborn period, the chest roentgenogram is generally normal. As pulmonary vascular resistance drops during the 1st several wk of life, evidence of increased pulmonary blood flow becomes apparent. Arterial Po_2 is low and does not rise appreciably after the patient breathes 100% oxygen (hyperoxia test), although this test may not be totally reliable. Echocardiography is diagnostic and confirms the transposed ventricular-arterial connections (Fig. 431-2). The size of the interatrial communication and the ductus arteriosus can be visualized and the degree of mixing assessed by pulsed and color Doppler examination. The presence of any associated lesion, such as left ventricular outflow tract obstruction or a VSD, can also be assessed. The origins of the coronary arteries can be imaged, although echocardiography is generally not as accurate as catheterization for this purpose. Cardiac

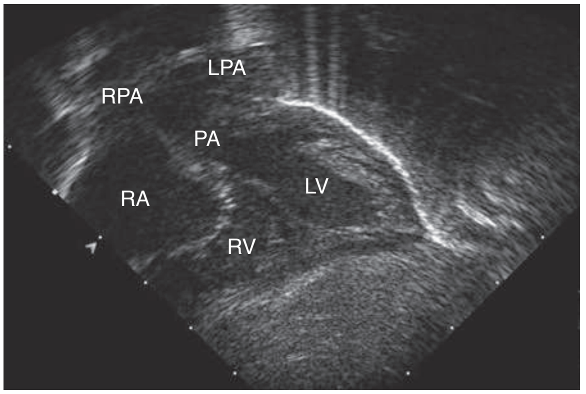

Figure 431-2 **Subcostal 4-chamber 2-dimensional echocardiographic demonstration of d-transposition of the great arteries.** The pulmonary artery (PA) can be seen arising directly from the left ventricle (LV). The immediate bifurcation of this great vessel into the branch pulmonary arteries differentiates it from the aorta, which branches more distally from the heart. LPA, left pulmonary artery; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle.

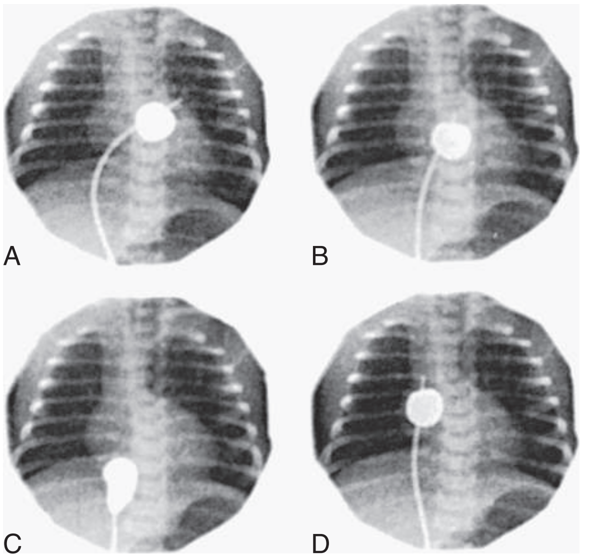

Figure 431-3 **Rashkind balloon atrial septostomy.** Four frames from a continuous cineangiogram show the creation of an atrial septal defect in a hypoxemic newborn infant with transposition of the great arteries and an intact ventricular septum. **A,** Balloon inflated in the left atrium. **B,** The catheter is jerked suddenly so that the balloon ruptures the foramen ovale. **C,** Balloon in the inferior vena cava. **D,** Catheter advanced to the right atrium to deflate the balloon. The time from **A** to **C** is <1 sec.

catheterization may be performed in patients for whom noninvasive imaging is diagnostically inconclusive, where an unusual coronary artery anomaly is suspected, or in patients who require emergency balloon atrial septostomy (Rashkind procedure). Catheterization will show right ventricular pressure to be systemic because this ventricle is supporting the systemic circulation. The blood in the left ventricle and pulmonary artery has a higher oxygen saturation than that in the aorta. Depending on the age at catheterization, left ventricular and pulmonary arterial pressure can vary from systemic level to <50% of systemic-level pressure. Right ventriculography demonstrates the anterior and rightward aorta originating from the right ventricle, as well as the intact ventricular septum. Left ventriculography shows that the pulmonary artery arises exclusively from the left ventricle.

Anomalous coronary arteries are noted in 10-15% of patients and defined by an aortic root injection or by selective coronary arteriography.

TREATMENT

When transposition is suspected, an infusion of prostaglandin E_1 should be initiated immediately to maintain patency of the ductus arteriosus and improve oxygenation (dosage: 0.01-0.20 µg/kg/min). Because of the risk of apnea associated with prostaglandin infusion, an individual skilled in neonatal endotracheal intubation should be available. Hypothermia intensifies the metabolic acidosis resulting from hypoxemia, and thus the patient should be kept warm. Prompt correction of acidosis and hypoglycemia is essential.

Infants who remain severely hypoxic or acidotic despite prostaglandin infusion should undergo **Rashkind balloon atrial septostomy** (Fig. 431-3). A Rashkind atrial septostomy is also usually performed in all patients in whom any significant delay in surgery is necessary. If surgery is planned during the 1st 2 wk of life, and the patient is stable, catheterization and atrial septostomy may be avoided.

A successful Rashkind atrial septostomy should result in a rise in PaO_2 to 35-50 mm Hg and elimination of any pressure gradient across the atrial septum. Some patients with TGA and VSD (see Chapter 431.3) may require balloon atrial septostomy because of poor mixing, even though the VSD is large. Others may benefit from decompression of the left atrium to alleviate the symptoms of increased pulmonary blood flow and left-sided heart failure.

The **arterial switch (Jatene) procedure** is the surgical **treatment of choice** for neonates with d-TGA and an intact ventricular septum and is usually performed within the 1st 2 wk of life. The reason for this time frame is that as pulmonary vascular resistance declines after birth, pressure in the left ventricle (connected to the pulmonary vascular bed) also declines. This drop in pressure results in a decrease in left ventricular mass over the 1st few wk of life. If the arterial switch operation is attempted after left ventricular pressure (and mass) has declined too far, the left ventricle will be unable to generate adequate pressure to pump blood to the high pressure systemic circulation. The arterial switch operation involves dividing the aorta and pulmonary artery just above the sinuses and reanastomosing them in their correct anatomic positions. The coronary arteries are removed from the old aortic root along with a button of aortic wall and reimplanted in the old pulmonary root (the "neoaorta"). By using a button of great vessel tissue, the surgeon avoids having to suture directly onto the coronary artery (Fig. 431-4); this is the major innovation that has allowed the arterial switch to replace previous atrial switch operations for d-TGA. Rarely, a 2-stage arterial switch procedure, with initial placement of a pulmonary artery band, may be used in patients presenting late who already have had a reduction in left ventricular muscle mass and pressure.

The arterial switch procedure has a survival rate of >95% for uncomplicated d-TGA. It restores the normal physiologic relationships of systemic and pulmonary arterial blood flow and eliminates the long-term complications of the previously used atrial switch procedure.

Previous operations for d-TGA consisted of some form of **atrial switch procedure** (**Mustard** or **Senning** operation). These procedures produced excellent early survival (≈85-90%), but had significant long-term morbidities. Atrial switch procedures reverse blood flow at the atrial level by the creation of an interatrial baffle that directs systemic venous blood returning from the vena cavae to the left atrium, where it will enter the left ventricle and then, via the pulmonary artery, the lungs. The same baffle also permits oxygenated pulmonary venous blood to cross over to the right atrium, right ventricle, and aorta. Atrial switch procedures involve significant atrial surgery and have been associated with the late development of atrial conduction disturbances, sick sinus syndrome with bradyarrhythmia and tachyarrhythmia, atrial flutter, sudden death, superior or inferior vena cava syndrome, edema, ascites, and protein-losing enteropathy. The atrial switch procedure also leaves the right ventricle as the systemic pumping chamber and these "systemic" right ventricles often begin to fail in young adulthood. Atrial

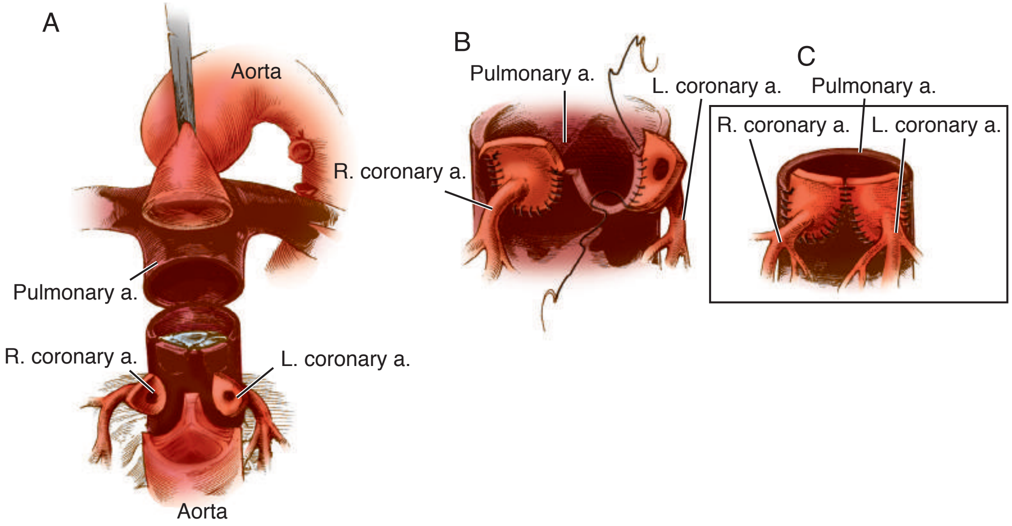

Figure 431-4 **Method for translocating the coronary arteries in the arterial switch (Jatene) procedure. A,** The aorta (anterior) and the pulmonary artery (posterior) have been transected to allow visualization of the left and right coronary arteries. The coronaries have been excised from their respective sinuses, including a large flap (button) of arterial wall. Equivalent segments of the wall of the pulmonary artery (which will become the neoaorta) are also removed. **B,** The aortocoronary buttons are sutured into the proximal portion of the neoaorta. With this technique all sutures are placed in the button of aortic wall rather than directly on the coronary arteries. **C,** Completed anastomosis of the left and right coronary arteries to the neoaorta. *(Adapted from Castañeda AR, Jonas RA, Mayer JE Jr, et al:* Cardiac surgery of the neonate and infant, *Philadelphia, 1994, WB Saunders.)*

switch operations are currently reserved for patients whose anatomy is such that they are not candidates for the arterial switch procedure.

431.3 Transposition of the Great Arteries with Ventricular Septal Defect

Daniel Bernstein

If the VSD associated with d-TGA is small, the clinical manifestations, laboratory findings, and treatment are similar to those described previously for transposition with an intact ventricular septum. A harsh systolic murmur is audible at the lower left sternal border, resulting from flow through the defect. Many of these small defects eventually close spontaneously and may not be addressed at the time of surgery.

When the VSD is large and not restrictive to ventricular ejection, significant mixing of oxygenated and deoxygenated blood usually occurs and clinical manifestations of cardiac failure are seen. The degree of cyanosis may be subtle and sometimes may not be recognized until an oxygen saturation measurement is performed. The murmur is holosystolic and generally indistinguishable from that produced by a large VSD in patients with normally related great arteries. The heart is usually significantly enlarged.

Cardiomegaly, a narrow mediastinal waist, and increased pulmonary vascularity are demonstrated on the chest x-ray. The electrocardiogram shows prominent P waves and isolated right ventricular hypertrophy or biventricular hypertrophy. Occasionally, dominance of the left ventricle is present. Usually, the QRS axis is to the right, but it can be normal or even to the left. The diagnosis is confirmed by echocardiography, and the extent of pulmonary blood flow can also be assessed by the degree of enlargement of the left atrium and ventricle. In equivocal cases, the diagnosis can be confirmed by cardiac catheterization. Right and left ventriculography indicate the presence of arterial transposition and demonstrate the site and size of the VSD. Systolic pressure is equal in the 2 ventricles, the aorta, and the pulmonary artery. Left atrial pressure may be much higher than right atrial pressure, a finding indicative of a restrictive communication at the atrial level. At the time of cardiac catheterization, Rashkind balloon atrial septostomy may be performed to decompress the left atrium, even when adequate mixing is occurring at the ventricular level.

Surgical treatment is advised soon after diagnosis, because heart failure and failure to thrive are difficult to manage and pulmonary vascular disease can develop unusually rapidly in these patients. Preoperative management with diuretics lessens the symptoms of heart failure and stabilizes the patient prior to surgery.

Patients with d-TGA and a VSD without pulmonic stenosis can be treated with an arterial switch procedure combined with VSD closure. In these patients, the arterial switch operation can be safely performed after the 1st 2 wk of life because the VSD results in equal pressure in both ventricles and prevents regression of left ventricular muscle mass. At major centers, however, there is no reason to delay repair, as results are excellent whether the surgery is performed in the neonatal period or later.

431.4 L-Transposition of the Great Arteries (Corrected Transposition)

Daniel Bernstein

In l-transposition (l-TGA), the atrioventricular relationships are discordant: the right atrium is connected to the left ventricle and the left atrium to the right ventricle (also known as *ventricular inversion*). The great arteries are also transposed, with the aorta arising from the right ventricle and the pulmonary artery from the left. In contrast to d-TGA, the aorta arises to the left of the pulmonary artery (hence the designation *l* for levo-transposition). The aorta may be anterior to the pulmonary artery, although often they are nearly side by side.

The physiology of l-TGA is quite different from that of d-TGA. Desaturated systemic venous blood returns via the vena cavae to a normal right atrium, from which it passes through a bicuspid atrioventricular (mitral) valve into a right-sided ventricle that has the architecture and smooth wall morphologic features of the normal left ventricle (Fig. 431-5). Because transposition is also present, however, the desaturated blood ejected from this left ventricle enters the transposed pulmonary artery and flows into the lungs, as it would in the normal circulation. Oxygenated pulmonary venous blood returns to a normal left atrium, passes through a tricuspid atrioventricular valve into a left-sided ventricle, which has the trabeculated morphologic features of a normal right ventricle, and is then ejected into the

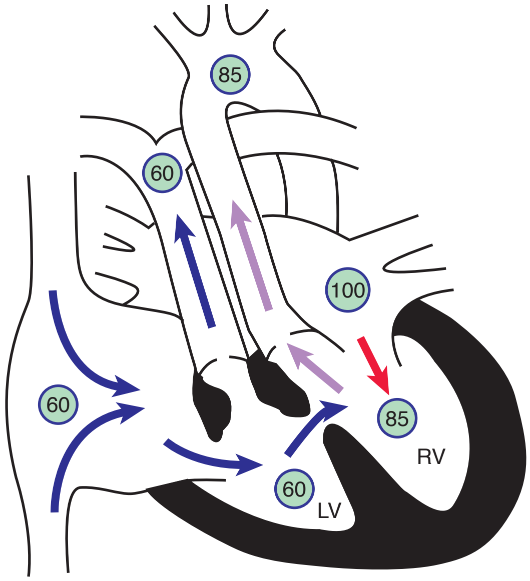

Figure 431-5 Physiology of l- or corrected transposition of the great arteries (l-TGA) with a ventricular septal defect and pulmonic stenosis (VSD + PS). *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Blood from the right atrium flows through the mitral valve into the "inverted" left ventricle (LV). The left ventricle is, however, attached to the transposed pulmonary artery. Therefore, despite the anomalies, desaturated blood still winds up in the pulmonary circulation. Saturated blood returns to the left atrium, traverses the tricuspid valve into the "inverted" right ventricle (RV), and is pumped into the transposed aorta. This circulation would be totally "corrected" were it not for the frequent association of other congenital anomalies, in this case, VSD + PS. Because of the stenotic pulmonary valve, some left ventricular blood flow crosses the VSD and into the right ventricle and the ascending aorta, and systemic desaturation results.

transposed aorta. The double inversion of the atrioventricular and ventriculoarterial relationships result in desaturated right atrial blood appropriately flowing to the lungs and oxygenated pulmonary venous blood appropriately flowing to the aorta. The circulation is thus physiologically **"corrected."** Without other defects, the hemodynamics would be nearly normal. In most patients, however, associated anomalies coexist: VSD, Ebstein-like abnormalities of the left-sided atrioventricular (tricuspid) valve, pulmonary valvular or subvalvular stenosis (or both), and atrioventricular conduction disturbances (complete heart block, accessory pathways such as Wolff-Parkinson-White syndrome).

CLINICAL MANIFESTATIONS

Symptoms and signs are widely variable and are determined by the associated lesions. If pulmonary outflow is unobstructed, the clinical signs are similar to those of an isolated VSD. If l-TGA is associated with pulmonary stenosis and a VSD, the clinical signs are more similar to those of tetralogy of Fallot.

DIAGNOSIS

The chest x-ray may suggest the abnormal position of the great arteries; the ascending aorta occupies the upper left border of the cardiac silhouette and has a straight profile. The electrocardiogram, in addition to any atrioventricular conduction disturbances, may show abnormal P waves; absent Q waves in V_6; abnormal Q waves in leads III, aVR, aVF, and V_1; and upright T waves across the precordium. The echocardiogram is diagnostic. The characteristic echocardiographic features of the right ventricle (moderator band, coarser trabeculations, tricuspid valve that sits more inferiorly compared to the bicuspid mitral valve, and a smooth muscular conus or infundibulum separating the atrioventricular valve from the semilunar valve) allow the echocardiographer to determine the presence of atrioventricular discordance (right atrium connected to left ventricle; left atrium to right ventricle).

Surgical treatment of the associated anomalies, most often the VSD, is complicated by the position of the bundle of His, which can be injured at the time of surgery and result in heart block. Identification of the usual course of the bundle in corrected transposition (running superior to the defect) has been accomplished by mapping of the conduction system so that the surgeon can avoid the bundle of His during repair. Even without surgical injury, patients with l-TGA are at risk for heart block as they grow older.

Because simple surgical correction leaves the right ventricle as the systemic pumping chamber, and hence vulnerable to late ventricular failure, surgeons have become more aggressive about trying operations that utilize the left ventricle as the systemic pumping chamber. This is accomplished by performing an atrial switch operation, to reroute the systemic and pulmonary venous returns, in combination with an arterial switch operation to reroute the ventricular outflows **(double switch procedure).** The long-term benefit of this approach in preserving systemic ventricular function is still under investigation.

431.5 Double-Outlet Right Ventricle Without Pulmonary Stenosis

Daniel Bernstein

In double-outlet right ventricle without pulmonary stenosis, both the aorta and the pulmonary artery arise from the right ventricle (see Chapter 430.5). The only outlet from the left ventricle is through a VSD. In the absence of obstruction to pulmonary blood flow, clinical manifestations are similar to those of an uncomplicated VSD with a large left-to-right shunt, although mild systemic desaturation may be present because of mixing of oxygenated and deoxygenated blood in the right ventricle. The electrocardiogram usually shows biventricular hypertrophy. Echocardiography is diagnostic and shows the right ventricular origin of both great arteries, their anteroposterior relationship, as well as the relationship of the VSD to each of the great arteries. Surgical correction is dependent on these relationships. If the VSD is subaortic, it is accomplished by creation of an intracardiac tunnel. Blood is then ejected from the left ventricle via the VSD into the aorta. If the VSD is subpulmonic, an arterial switch may be performed in combination with an intracardiac tunnel. If pulmonary blood flow is excessive enough to cause congestive heart failure, pulmonary arterial banding may be required in infancy, followed by surgical correction when the child is bigger. When associated pulmonary stenosis is present, cyanosis is more marked, pulmonary blood flow is decreased, and clinical presentation may be similar to that of tetralogy of Fallot (see Chapter 430.5).

431.6 Double-Outlet Right Ventricle with Malposition of the Great Arteries (Taussig-Bing Anomaly)

Daniel Bernstein

In double-outlet right ventricle with malposed great arteries, the VSD is usually directly subpulmonary and the aorta distant from the left ventricle. Sometimes both the pulmonary and aortic valves may be located close to the VSD (doubly committed VSD) and sometimes neither is (doubly uncommitted VSD). The term *malposition* is used instead of *transposition* because both great arteries arise from the right ventricle. Aortic obstructive lesions are common, including valvular

and subvalvular aortic stenosis, coarctation of the aorta, and interruption of the aortic arch. Because pulmonary blood flow is unobstructed, patients experience cardiac failure early in infancy and are at risk for the development of pulmonary vascular disease and cyanosis. If aortic obstructive lesions are a component, patients can present with poor systemic output and cardiovascular collapse, particularly after the ductus begins to close. Cardiomegaly is usual, and a parasternal systolic ejection murmur is audible, sometimes preceded by an ejection click and loud closure of the pulmonary valve. The electrocardiogram shows right axis deviation and right, left, or biventricular hypertrophy. The chest x-ray shows cardiomegaly and prominence of the pulmonary vasculature. The anatomic features of the anomaly and associated abnormalities are usually demonstrated by echocardiography, augmented if necessary by either cardiac catheterization, MRI, or CT. Palliation may be achieved by pulmonary arterial banding in infancy and surgical correction at a later age, which may be accomplished by an arterial switch procedure (see Chapter 431.2) combined with an intracardiac baffle, or some modification of the Rastelli procedure (see Chapter 430.5).

431.7 Total Anomalous Pulmonary Venous Return

Daniel Bernstein

PATHOPHYSIOLOGY

Abnormal development of the pulmonary veins may result in either partial or complete anomalous drainage into the systemic venous circulation. Partial anomalous pulmonary venous return is usually an acyanotic lesion (see Chapter 426.4). Total anomalous pulmonary venous return (TAPVR) is associated with total mixing of systemic venous and pulmonary venous blood flow within the heart and thus produces cyanosis.

In TAPVR, the heart has no direct pulmonary venous connection into the left atrium. The pulmonary veins may drain above the diaphragm into the right atrium directly, into the coronary sinus, or into the superior vena cava via a "vertical vein," or they may drain below the diaphragm and join into a "descending vein" that enters into the inferior vena cava or one of its major tributaries, often via the ductus venosus. This latter form of anomalous venous drainage is most commonly associated with obstruction to venous flow, usually as the ductus venosus closes soon after birth, although supracardiac anomalous veins may also become obstructed. Occasionally, the drainage may be mixed, with some veins draining above and others below the diaphragm.

All forms of TAPVR involve mixing of oxygenated and deoxygenated blood before or at the level of the right atrium (total mixing lesion). This mixed right atrial blood either passes into the right ventricle and pulmonary artery or passes through an atrial septal defect (ASD) or patent foramen ovale into the left atrium, which will be the only source of systemic blood flow. The right atrium and ventricle and the pulmonary artery are generally enlarged, whereas the left atrium and ventricle may be normal or small. The clinical manifestations of TAPVR depend on the presence or absence of obstruction of the venous channels (Table 431-1). If pulmonary venous return is obstructed, severe pulmonary congestion and pulmonary hypertension develop; rapid deterioration occurs without surgical intervention. Obstructed TAPVR is a pediatric cardiac surgical emergency because prostaglandin therapy is usually not effective.

CLINICAL MANIFESTATIONS

Two major clinical patterns of TAPVR are seen, depending on the presence or absence of obstruction. Those neonates with severe obstruction to pulmonary venous return, most prevalent in the infracardiac group (see Table 431-1), present with severe cyanosis and respiratory distress. Murmurs may not be present. These infants are severely ill and fail to respond to mechanical ventilation. Rapid diagnosis and surgical correction are necessary for survival. In contrast, those with mild or no obstruction to pulmonary venous return are usually characterized by the development of heart failure as the pulmonary vascular resistance falls, with mild to moderate degrees of desaturation. Systolic murmurs may be audible along the left sternal border, and a gallop rhythm may be present. Some infants may have mild obstruction in the neonatal period and develop worsening obstruction as time passes.

DIAGNOSIS

The electrocardiogram demonstrates right ventricular hypertrophy (usually a qR pattern in V_3R and V_1, and the P waves are frequently tall and spiked). In neonates with marked pulmonary venous obstruction, the chest x-ray demonstrates a very dramatic perihilar pattern of pulmonary edema and a small heart. This appearance can sometimes be confused with primary pulmonary disease and the differential diagnosis includes persistent pulmonary hypertension of the newborn, respiratory distress syndrome, pneumonia (bacterial, meconium aspiration), pulmonary lymphangiectasia, and other heart defects (hypoplastic left heart syndrome). In older children, if the anomalous pulmonary veins enter the innominate vein and persistent left superior vena cava (Fig. 431-6), a large supracardiac shadow can be seen, which together with the normal cardiac shadow forms a **"snowman"** appearance. In most cases without obstruction, the heart is enlarged, the pulmonary artery and right ventricle are prominent, and pulmonary vascularity is increased.

The echocardiogram demonstrates a large right ventricle and usually identifies the pattern of abnormal pulmonary venous connections (Fig. 431-7). The demonstration of any vein with Doppler flow away from the heart is pathognomonic of TAPVR as normal venous flow is usually toward the heart. Shunting occurs from right to left at the atrial level. The size of the left atrium and left ventricle can be measured and the presence of any associated cardiac defects determined.

Echocardiography should be adequate to demonstrate TAPVR in most cases; however, if there is question about the drainage of 1 or more pulmonary veins, cardiac catheterization, MRI, or CT is performed. Catheterization shows that the oxygen saturation of blood in both atria, both ventricles, and the aorta is similar, indicative of a total mixing lesion. An increase in systemic venous saturation occurs at the site of entry of the abnormal pulmonary venous channel, either above or below the diaphragm. In older patients, pulmonary arterial and right ventricular pressure may be only moderately elevated, but in infants with pulmonary venous obstruction, pulmonary hypertension is usual. Selective pulmonary arteriography shows the anatomy of the pulmonary veins and their point of entry into the systemic venous circulation.

TREATMENT

Surgical correction of TAPVR is indicated during infancy, with emergent repair performed for those patients with venous obstruction. If

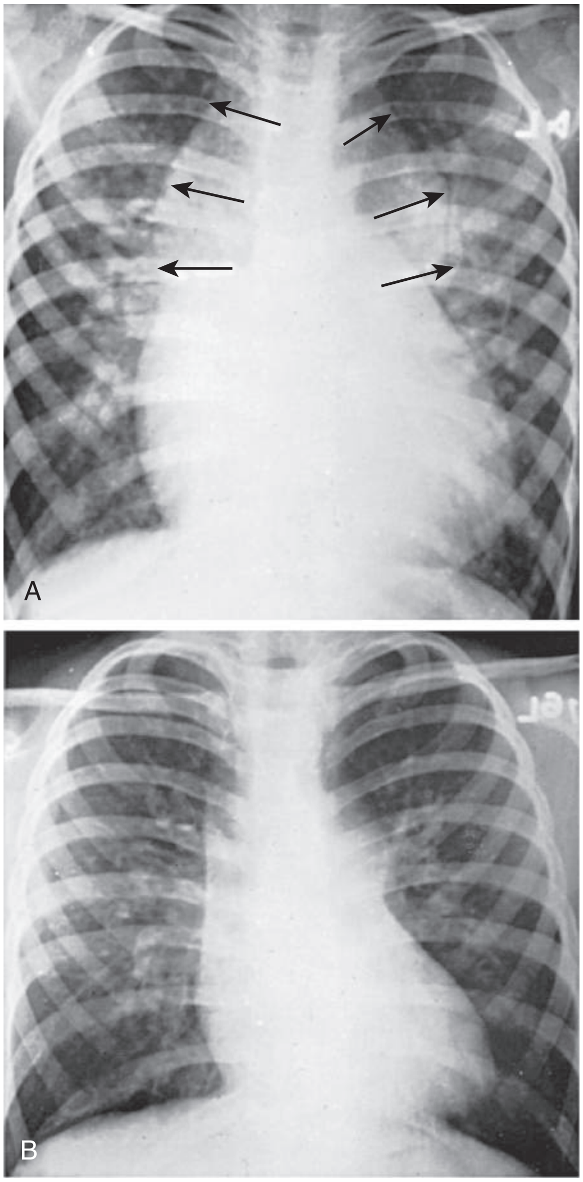

Figure 431-6 Chest x-ray of total anomalous pulmonary venous return to the left superior vena cava. **A,** Preoperative image. *Arrows* point to the supracardiac shadow, which produces the snowman or figure-8 configuration. Cardiomegaly and increased pulmonary vascularity are evident. **B,** Postoperative image showing a decrease in the size of the heart and the supracardiac shadow.

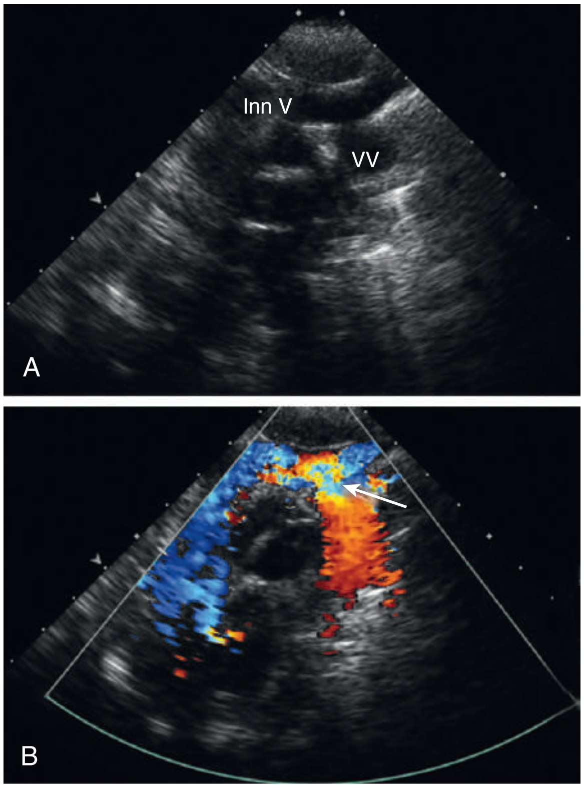

Figure 431-7 Suprasternal 2-dimensional echocardiographic views demonstrating supracardiac total anomalous pulmonary venous return (type I). **A,** The large vertical ascending vein can be seen entering the innominate vein. There is a moderate narrowing where the anomalous vein enters the upper body venous system. **B,** Color Doppler examination shows a venous flow signal *(red color)* indicating that blood is moving away toward the transducer and thus from the heart (all venous flow should normally return toward the heart), diagnostic of anomalous pulmonary venous return. The turbulent acceleration of flow can be seen *(arrow)* where the vertical vein enters the innominate. Inn V, innominate vein; VV, vertical vein.

surgery cannot be performed urgently, extracorporeal membrane oxygenation may be required to maintain oxygenation. Surgically, the pulmonary venous confluence is anastomosed directly to the left atrium, the ASD is closed, and any connection to the systemic venous circuit is interrupted. Early results are generally good, even for critically ill neonates. The postoperative period may be complicated by pulmonary vascular hypertensive crises. In some patients, especially those in whom the diagnosis was delayed or the obstruction was severe, recurrent stenosis and development of pulmonary veno-occlusive disease may occur. Attempts have been made to treat recurrent stenosis with surgery, balloon angioplasty, stents, and antiproliferative chemotherapy. To date, the long-term prognosis in these patients is very guarded and in those with aggressive veno-occlusive disease, **heart-lung transplantation** may be the only option (see Chapter 443.2).

Bibliography is available at Expert Consult.

431.8 Truncus Arteriosus

Daniel Bernstein

PATHOPHYSIOLOGY

In truncus arteriosus, a single arterial trunk (truncus arteriosus) arises from the heart and supplies the systemic, pulmonary, and coronary circulations. A VSD is always present, with the truncus overriding the defect and receiving blood from both the right and left ventricles (Fig. 431-8). The number of truncal valve cusps varies from 2 to as many as 6 and the valve may be stenotic, regurgitant, or both. The pulmonary arteries can arise together from the posterior left side of the persistent truncus arteriosus and then divide into left and right pulmonary arteries **(type I).** In **types II** and **III** truncus arteriosus, no main pulmonary artery is present, and the right and left pulmonary arteries arise from separate orifices on the posterior **(type II)** or lateral **(type III)** aspects of the truncus arteriosus. **Type IV** truncus is a term no longer used because, in this case, there is no identifiable connection between the heart and pulmonary arteries, and pulmonary blood flow is derived from major aortopulmonary collateral arteries arising from the transverse or descending aorta; this is essentially a form of pulmonary atresia (see Chapter 430.2).

Both ventricles are at systemic pressure and both eject blood into the truncus. When pulmonary vascular resistance is relatively high immediately after birth, pulmonary blood flow may be normal; as pulmonary resistance drops in the 1st mo of life, blood flow to the lungs is greatly increased and heart failure ensues. Truncus arteriosus is a total mixing lesion with complete admixture of pulmonary and systemic venous return. Because of the large volume of pulmonary

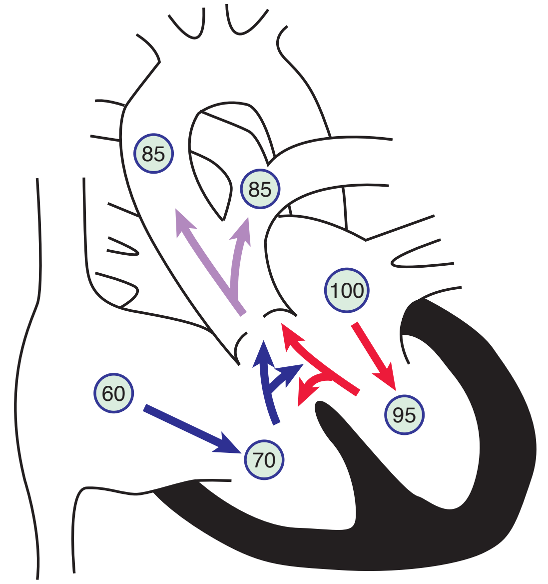

Figure 431-8 **Physiology of truncus arteriosus.** *Circled numbers* represent oxygen saturation values. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Desaturated blood enters the right atrium, flows through the tricuspid valve into the right ventricle, and is ejected into the truncus. Saturated blood returning from the left atrium enters the left ventricle and is also ejected into the truncus. The common aortopulmonary trunk gives rise to the ascending aorta and to the main or branch pulmonary arteries. Oxygen saturation in the aorta and pulmonary arteries is usually the same (definition of a total mixing lesion). As pulmonary vascular resistance decreases in the 1st few wk of life, pulmonary blood flow increases dramatically and mild cyanosis and congestive heart failure result.

blood flow, clinical cyanosis is usually mild. If the lesion is left untreated, pulmonary resistance eventually increases, pulmonary blood flow decreases, and cyanosis becomes more prominent (Eisenmenger physiology; see Chapter 433.2).

CLINICAL MANIFESTATIONS

The clinical signs of truncus arteriosus vary with age and depend on the level of pulmonary vascular resistance. In the immediate newborn period, signs of heart failure are usually absent; a murmur and minimal cyanosis may be the only initial findings. Over the next 1-2 mo of life, pulmonary blood flow begins to become torrential and the clinical picture is dominated by heart failure, with still mild cyanosis. Runoff of blood from the truncus to the pulmonary circulation may result in a wide pulse pressure and bounding pulses. These findings will be further exaggerated if truncal valve insufficiency is present. The heart is usually enlarged, and the precordium is hyperdynamic. The 2nd heart sound is loud and single. A systolic ejection murmur, sometimes accompanied by a thrill, is generally audible along the left sternal border. The murmur is frequently preceded by an early systolic ejection click due to the abnormal truncal valve. In the presence of truncal valve insufficiency, a high-pitched early diastolic decrescendo murmur is heard at the mid-left sternal border. An apical mid-diastolic rumbling murmur caused by increased flow through the mitral valve is often audible with the bell of the stethoscope, especially as heart failure develops. Truncus arteriosus is a conotruncal malformation and may be associated with **DiGeorge syndrome,** linked to a deletion of a large region of chromosome 22q11 (see Chapter 424).

DIAGNOSIS

The electrocardiogram shows right, left, or combined ventricular hypertrophy. The chest x-ray also shows considerable variation. Cardiac enlargement will develop over the 1st several wk of life, and is a result of the prominence of both ventricles. The truncus may produce a prominent shadow that follows the normal course of the ascending aorta and aortic knob; the aortic arch is right-sided in 50% of patients. Sometimes

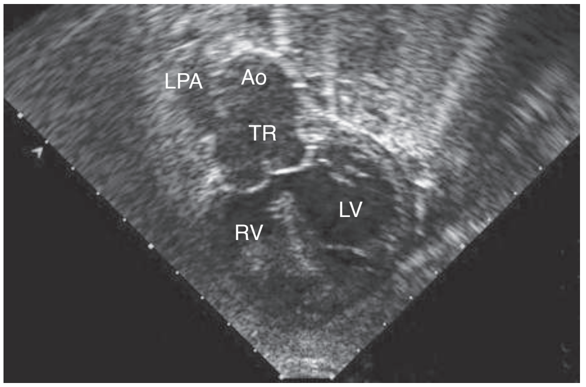

Figure 431-9 **Subcostal 2-dimensional echocardiographic demonstration of truncus arteriosus.** The large truncal valve can be seen overriding the ventricular septal defect. In this case, only the left pulmonary artery (*LPA*) arises from the truncus (*TR*). The pulmonary arteries are discontinuous and the right pulmonary artery arises from the descending aorta via the ductus arteriosus (not shown). Ao, aorta; LV, left ventricle; RV, right ventricle.

a high bulge left of the aortic knob is produced by the main or left pulmonary artery. Pulmonary vascularity is increased after the 1st few wk of life. Echocardiography is diagnostic and demonstrates the large truncal artery overriding the VSD and the pattern of origin of the branch pulmonary arteries (Fig. 431-9). Associated anomalies such as an interrupted aortic arch may be noted. Pulsed and color Doppler studies are used to evaluate truncal valve regurgitation. If required, cardiac catheterization shows a left-to-right shunt at the ventricular level, with right-to-left shunting into the truncus. Systolic pressure in both ventricles and the truncus is similar. Angiography reveals the large truncus arteriosus and more defines the origin of the pulmonary arteries.

PROGNOSIS AND COMPLICATIONS

Surgical results have been excellent, and many patients with repaired truncus are now entering adulthood. The need to replace the right ventricular to pulmonary artery conduit as the child grows means that these patients will need to undergo multiple operations by the time they reach adulthood. When truncus arteriosus is associated with DiGeorge syndrome, the associated endocrine, immunologic, craniofacial, and airway abnormalities may complicate recovery.

TREATMENT

In the 1st few wk of life, many of these infants can be managed with anticongestive medications; as pulmonary vascular resistance falls, heart failure symptoms worsen and surgery is indicated, usually within the 1st few mo. Delay of surgery much beyond this time period may increase the likelihood of pulmonary vascular disease; many centers now perform routine neonatal repair at the time of diagnosis. At surgery, the VSD is closed, the pulmonary arteries are separated from the truncus, and continuity is established between the right ventricle and the pulmonary arteries with a homograft conduit. Immediate surgical results are excellent, but these conduits will develop either regurgitation or stenosis over time, and must be replaced, often several times, as the child grows. If regurgitation is the primary problem, patients can now be treated with a transcatheter stent-valve.

Bibliography is available at Expert Consult.

431.9 Single Ventricle (Double-Inlet Ventricle, Univentricular Heart)

Daniel Bernstein

PATHOPHYSIOLOGY

With a single ventricle, both atria empty through a common atrioventricular valve or via 2 separate valves into a single ventricular chamber, with total mixing of systemic and pulmonary venous return. This

chamber may have left, right, or indeterminate ventricular anatomic characteristics. The aorta and pulmonary artery both arise from this single chamber, although one of the great vessels may originate from a rudimentary outflow chamber. The aorta may be posterior, anterior (malposition), or side by side with the pulmonary artery and either to the right or to the left. Pulmonary stenosis or atresia is common.

CLINICAL MANIFESTATIONS

The clinical picture is variable and depends on the associated intracardiac anomalies. If pulmonary outflow is obstructed, the findings are usually similar to those of tetralogy of Fallot: marked cyanosis without heart failure. If pulmonary outflow is unobstructed, the findings are similar to those of transposition with VSD: minimal cyanosis with increasing heart failure.

In patients with **pulmonary stenosis**, cyanosis is present in early infancy. Cardiomegaly is mild or moderate, a left parasternal lift is palpable, and a systolic thrill is common. The systolic ejection murmur is usually loud; an ejection click may be audible, and the 2nd heart sound is single and loud. In patients with **unobstructed pulmonary flow**, as pulmonary vascular resistance drops, torrential pulmonary blood flow develops, and these patients present with tachypnea, dyspnea, failure to thrive, and recurrent pulmonary infections. Cyanosis is only mild or moderate. Cardiomegaly is generally marked, and a left parasternal lift is palpable. A systolic ejection murmur is present but is not usually loud or harsh, and the 2nd heart sound is loud and closely split. A 3rd heart sound is common and may be followed by a short mid-diastolic rumbling murmur caused by increased flow through the atrioventricular valves. The eventual development of pulmonary vascular disease reduces pulmonary blood flow so that the cyanosis increases and signs of cardiac failure appear to improve (Eisenmenger physiology; see Chapter 433.2).

DIAGNOSIS

Findings on the electrocardiogram are nonspecific. P waves are normal, spiked, or bifid. The precordial lead pattern suggests right ventricular hypertrophy, combined ventricular hypertrophy, or sometimes left ventricular dominance. The initial QRS forces are usually to the left and anterior. Radiographic examination confirms the degree of cardiomegaly. If present, a rudimentary outflow chamber may produce a bulge on the upper left border of the cardiac silhouette in the posteroanterior projection. In the absence of pulmonary stenosis, pulmonary vasculature is increased, whereas in the presence of pulmonary stenosis, pulmonary vasculature is diminished. Echocardiography will confirm the absence or near absence of the ventricular septum and can usually determine whether the single ventricle has right, left, or mixed morphologic features. The presence of a rudimentary outflow chamber under one of the great vessels can be identified, and pulsed Doppler can be used to determine whether flow through this communication (known as a *bulboventricular foramen*) is obstructed.

If cardiac catheterization is performed, the pressure in the single ventricular chamber is at systemic level; however, a gradient may be demonstrated across the entrance to a rudimentary outflow chamber. Pressure measurements and angiography demonstrate whether pulmonary stenosis is present.

PROGNOSIS AND COMPLICATIONS

Unoperated, some patients succumb during infancy from heart failure. Others may survive to adolescence and early adult life but finally succumb to the effects of chronic hypoxemia or, in the absence of pulmonary stenosis, to the effects of pulmonary vascular disease. Patients with moderate pulmonary stenosis have the best prognosis because pulmonary blood flow, though restricted, is still adequate. Surgical palliation, eventually leading to Fontan-type circulatory physiology (see Chapter 430.4), has very good short- and intermediate-term results.

TREATMENT

If pulmonary stenosis is severe, a **Blalock-Taussig aortopulmonary shunt** is performed to provide a reliable source of pulmonary blood flow (see Chapter 430.1). If pulmonary blood flow is unrestricted, pulmonary arterial banding is used to control heart failure and prevent progressive pulmonary vascular disease. The **bidirectional Glenn shunt** is usually performed at between 2 and 6 mo of age, followed by a **modified Fontan operation** (cavopulmonary isolation procedure; see Chapter 430.4) at 2-3 yr of age. If subaortic stenosis is present because of a restrictive connection to a rudimentary outflow chamber, (restrictive bulboventricular foramen) surgical relief can be provided by anastomosing the proximal pulmonary artery to the side of the ascending aorta **(Damus-Stansel-Kaye operation).**

431.10 Hypoplastic Left-Heart Syndrome

Daniel Bernstein

PATHOPHYSIOLOGY

The term *hypoplastic left heart* is used to describe a related group of anomalies that include various degrees of underdevelopment of the left side of the heart: stenosis or atresia of the aortic and mitral valves and hypoplasia of the left ventricular cavity and ascending aorta. Two broad categories include aortic atresia with hypoplastic but perforate mitral valve or with mitral atresia. The left ventricle may be only moderately hypoplastic, very small and nonfunctional, or totally atretic; in the immediate neonatal period the right ventricle maintains both the pulmonary circulation and the systemic circulation via the ductus arteriosus (Fig. 431-10). Pulmonary venous blood passes through an ASD or dilated foramen ovale from the left to the right side of the heart, where it mixes with systemic venous blood **(total mixing lesion).**

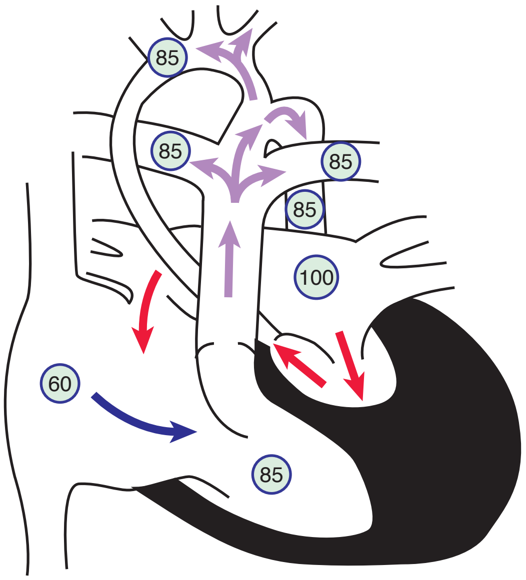

Figure 431-10 Physiology of hypoplastic left-heart syndrome (HLHS). *Circled numbers* represent oxygen saturation values. HLHS is not a single lesion but a constellation of different degrees of hypoplasia of the left-sided heart structures. This drawing shows a patent mitral valve, a small left ventricular cavity, and a diminutive ascending aorta. Right atrial (mixed venous) oxygen saturation is decreased secondary to systemic hypoxemia. Desaturated blood enters the right atrium, flows through the tricuspid valve into the right ventricle, and is ejected into the pulmonary artery. Because of the markedly decreased left ventricular compliance, most of the pulmonary venous blood returning to the left atrium shunts left to right at the atrial level. A small amount of left atrial blood will cross the mitral valve and be ejected into the tiny ascending aorta. The right ventricular oxygen saturation represents a mixing of desaturated systemic venous blood and saturated pulmonary venous blood. Pulmonary artery blood flows into the pulmonary arteries as well as right to left across the patent ductus arteriosus (PDA) into the aorta. Ductal blood flows prograde to the descending aorta as well as retrograde to the ascending aorta, where it supplies the head and neck vessels in addition to the coronary arteries (which arise off the small ascending aorta). Closure of the PDA results in profound hypoxia and circulatory collapse.

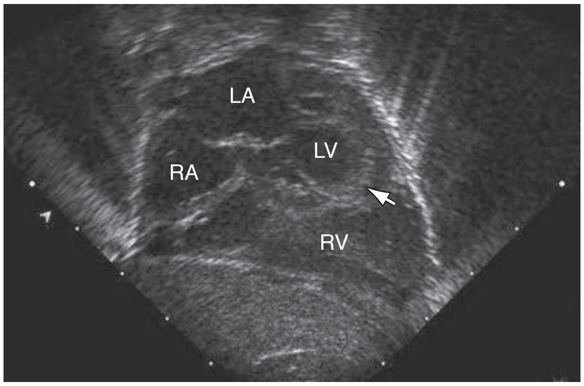

Figure 431-11 Subcostal 2-dimensional echocardiographic diagnosis of hypoplastic left-heart syndrome. The small left ventricular chamber can be seen, the apex of which *(arrowhead)* does not form the apex of the heart. The atrial septum can be seen bowing from the left to the right, indicating that the communication between the 2 atria is pressure restrictive. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

When the ventricular septum is intact, which is usually the case, all the right ventricular blood is ejected into the main pulmonary artery; the descending aorta is supplied via the ductus arteriosus, and flow from the ductus also fills the ascending aorta and coronary arteries in a retrograde fashion. The major hemodynamic abnormalities are inadequate maintenance of the systemic circulation and, depending on the size of the atrial-level communication, either pulmonary venous hypertension (restrictive foramen ovale) or pulmonary overcirculation (moderate or large ASD).

CLINICAL MANIFESTATIONS

Although cyanosis may not always be obvious in the 1st 48 hr of life, a grayish-blue color of the skin is soon apparent and denotes a mix of cyanosis and poor perfusion. The condition is diagnosed in most infants in the 1st few hr or days of life. Once the ductus arteriosus begins to closes, signs of poor systemic perfusion and shock predominate. All of the peripheral pulses may be weak or absent. A palpable right ventricular parasternal lift may be present along with a nondescript systolic murmur.

This lesion may be isolated or associated in 5-15% of patients with known genetic syndromes, such as Turner syndrome, trisomy 13, 18, or 21, Jacobsen syndrome (11q deletion), Holt-Oram syndrome, and Rubinstein-Taybi syndrome. In these circumstances, noncardiac manifestations of the syndrome may be evident and influence the clinical outcomes. Occasionally it is familial and inherited as an autosomal recessive trait.

DIAGNOSIS

On the chest x-ray, the heart is variable in size in the 1st days of life, but cardiomegaly develops rapidly and is associated with increased pulmonary vascularity. The initial electrocardiogram may show only the normal neonatal pattern of right ventricular dominance, but later, P waves become prominent and right ventricular hypertrophy is usual with reduced left ventricular forces. The echocardiogram is diagnostic and demonstrates absence or hypoplasia of the mitral valve and aortic root, a variably small left atrium and left ventricle, and a large right atrium and right ventricle (Fig. 431-11). The size of the atrial communication, by which pulmonary venous blood leaves the left atrium, can be assessed directly and by pulsed and color flow Doppler studies. The small ascending aorta and transverse aortic arch are identified and a discrete coarctation of the aorta in the juxtaductal area may be present, although in the presence of a large ductus, it may be difficult to identify. Doppler echocardiography demonstrates whether the mitral and aortic valves are severely stenotic or totally atretic. The presence of left ventricular coronary sinusoids can be identified. The diagnosis of hypoplastic left-heart syndrome can usually be made without need for cardiac catheterization. If catheterization is necessary, the hypoplastic ascending aorta is demonstrated by angiography.

PROGNOSIS AND COMPLICATIONS

Untreated patients most often succumb during the 1st few mo of life, usually during the 1st or 2nd wk. Occasionally, unoperated patients may live for months or, rarely, years. Up to 30% of infants with hypoplastic left-heart syndrome have evidence of either a major or minor central nervous system abnormality. Other dysmorphic features may be found in up to 40% of patients. Thus, careful preoperative evaluation (genetic, neurologic, ophthalmologic) should be performed in patients being considered for surgical therapy.

Intermediate-term follow up after completion of all 3 stages of the Norwood procedure demonstrates generally good exercise capacity, and complications equivalent to other patients who have had the Fontan palliation (see Chapter 430.4). Some studies show that patients with hypoplastic left-heart syndrome have a higher risk of neurodevelopmental problems than those with other complex congenital heart lesions. Whether the poor neurodevelopmental outcome is due to prenatal associated central nervous system injury or malformation, the alterations of cerebral hemodynamics during bypass surgery, or poor postoperative perfusion is unknown. In addition, poor outcome is associated with prematurity, chromosome syndromes, and poverty.

TREATMENT

Surgical therapy for hypoplastic left-heart syndrome is associated with improving survival rates, reported as high as 90-95% for the 1st-stage palliation in experienced centers. The 1st-stage repair is designed to construct a reliable source of systemic blood flow arising from the single right ventricle using a combination of aortic and pulmonary arterial tissue, and to limit pulmonary blood flow to avoid heart failure and prevent the development of pulmonary vascular disease. The 2 surgical procedures most commonly utilized are the **Norwood procedure** (Fig. 431-12) and the **Sano procedure.** Primary heart transplantation, previously advocated by a few centers, is much less common because of the substantially improved survival rates with standard surgery and the limited supply of donor organs in this age group.

If a Norwood or Sano procedure is to be performed, preoperative medical management includes correction of acidosis and hypoglycemia, maintenance of ductus arteriosus patency with prostaglandin E_1 (0.01-0.20 µg/kg/min) to support systemic blood flow, and prevention of hypothermia. Preoperative management should avoid excessive pulmonary blood flow; either through management of ventilator settings, increasing the concentration of inspired CO_2, or decreasing the concentration of inspired O_2. Balloon dilation of the atrial septum may be indicated.

The Norwood procedure is usually performed in 3 stages. **Stage I** (see Fig. 431-12) includes an atrial septectomy and transection and ligation of the distal main pulmonary artery; the proximal pulmonary artery is then connected to the transversely opened hypoplastic aortic arch to form a neoaorta, extending through the coarcted segment of the juxtaductal aortic arch. A synthetic aortopulmonary (Blalock-Taussig) shunt connects the aorta to the main pulmonary artery to provide controlled pulmonary blood flow. In the Sano modification, a right ventricle to pulmonary artery conduit is used instead of an aortopulmonary shunt to provide pulmonary blood flow, temporarily creating a double-outlet right ventricle. The operative risk for these 1st-stage procedures has improved dramatically in the past 2 decades and the best reported results demonstrate a 90-95% survival rate.

Stage II consists of a Glenn anastomosis to connect the superior vena cava to the pulmonary arteries (see Chapter 431.4), at between 2 and 6 mo of age. **Stage III**, usually performed at 2-3 yr of age, consists of a modified Fontan procedure (cavopulmonary isolation) to connect the inferior vena cava to the pulmonary arteries via either an intraatrial or external baffle. After **stage III,** all systemic venous return enters the pulmonary circulation directly. Pulmonary venous flow enters the left atrium and is directed across the atrial septum to the tricuspid valve and subsequently to the right (now the systemic) ventricle. Blood leaves the right ventricle via the neoaorta, which supplies the systemic

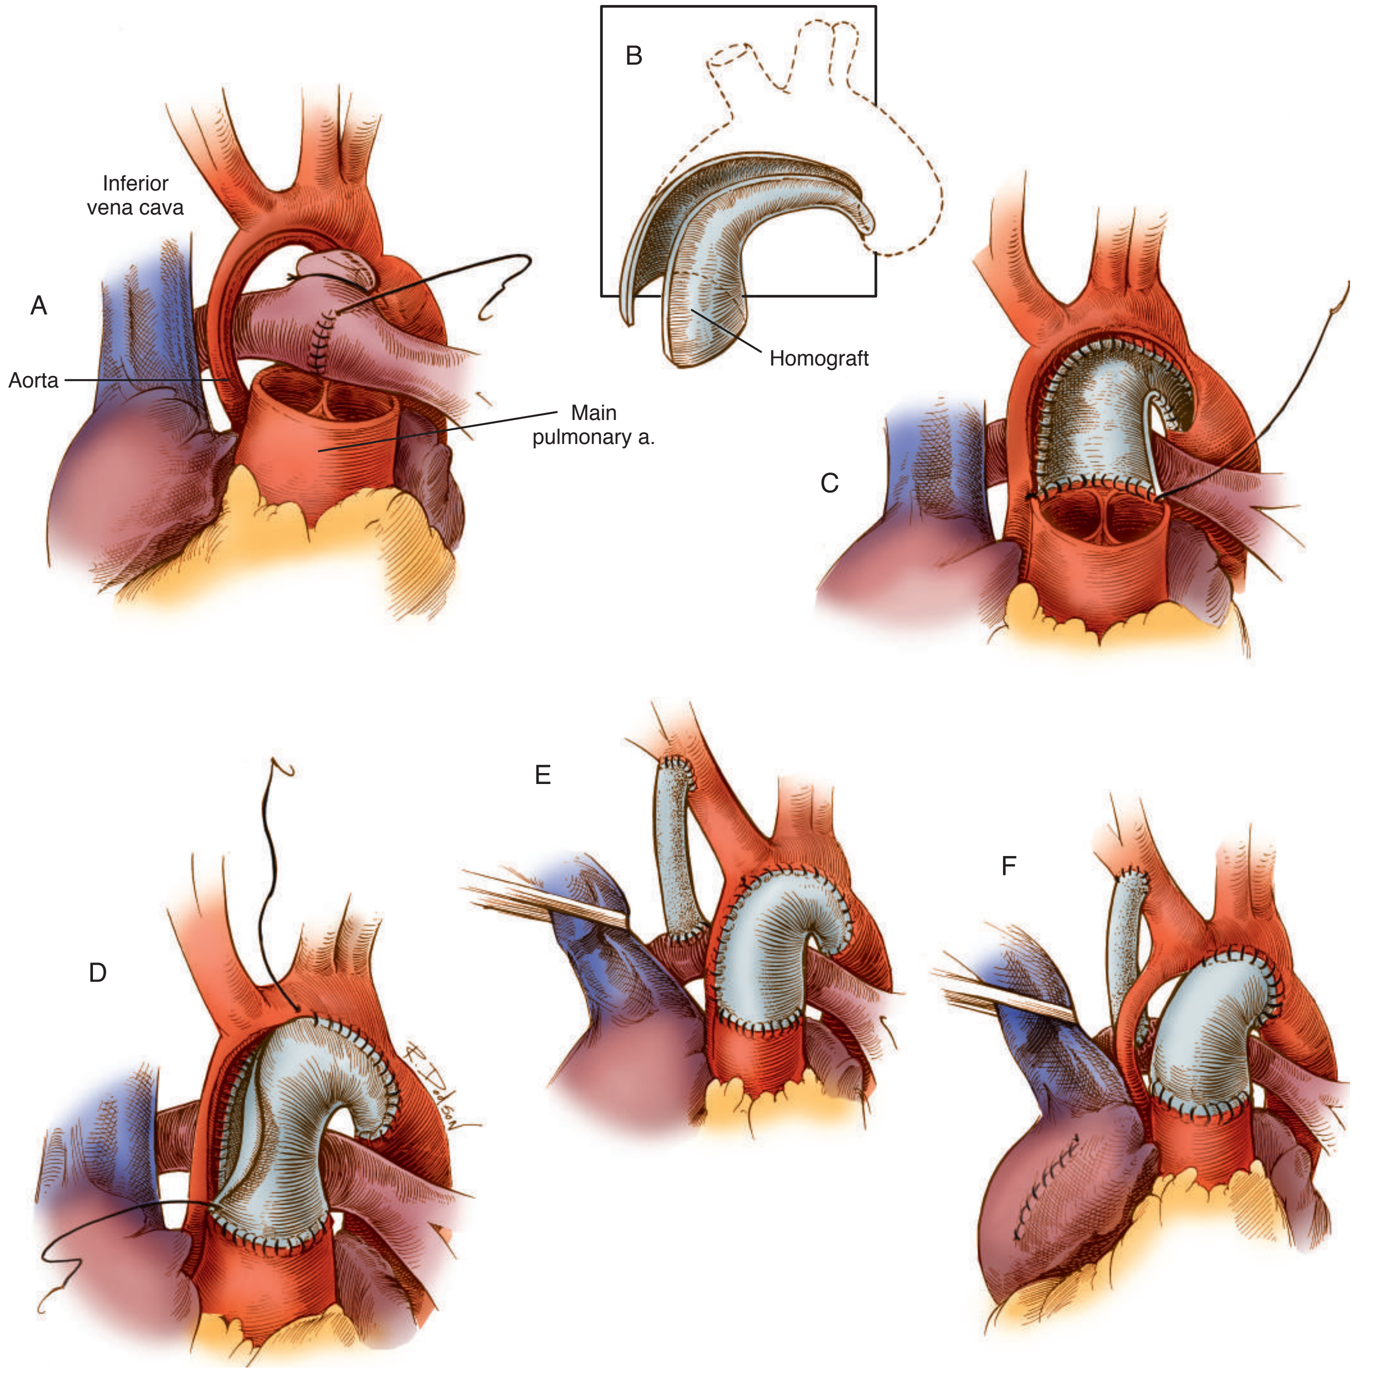

Figure 431-12 The Norwood procedure, 1 of the 2 current techniques for 1st-stage palliation of hypoplastic left-heart syndrome. **A,** Incisions used for the procedure incorporate a cuff of arterial wall allograft. The distal divided main pulmonary artery may be closed by direct suture or with a patch. **B,** Dimensions of the cuff of the arterial wall allograft. **C,** The arterial wall allograft is used to supplement the anastomosis between the proximal divided main pulmonary artery and the ascending aorta, aortic arch, and proximal descending aorta. **D** and **E,** The procedure is completed by an atrial septectomy and a 3.5-mm modified right Blalock shunt. **F,** When the ascending aorta is particularly small, an alternative procedure involves placement of a complete tube of arterial allograft. The tiny ascending aorta may be left in situ, as indicated, or implanted into the side of the neoaorta. *(From Castañeda AR, Jonas RA, Mayer JE Jr, et al: Single-ventricle tricuspid atresia. In* Cardiac surgery of the neonate and infant, *Philadelphia, 1994, WB Saunders.)*

circulation. The old aortic root now attached to the neoaorta provides coronary blood flow. The risks associated with stages II and III are even less than those of stage I; interstage mortality (usually between stages I and II) has been reduced with the use of home monitoring programs. The short- and long-term benefits of using the Norwood versus the Sano procedure remain to be demonstrated.

An alternative therapeutic approach is to perform a **hybrid procedure** for the 1st stage. This involves performing a Rashkind balloon atrial septostomy, catheter placement of a stent in the ductus arteriosus, and surgical placement of bilateral pulmonary artery bands. After the hybrid procedure, patients can be weaned off prostaglandin and discharged from hospital. After the hybrid procedure, patients need to undergo a more extensive 2nd-stage procedure involving construction of a neoaorta and removal of the pulmonary artery bands.

Another alternative therapy is **cardiac transplantation,** either in the immediate neonatal period, thereby obviating stage I of the Norwood procedure, or after a successful stage I Norwood procedure is performed as a bridge to transplantation. After transplantation, patients usually have normal cardiac function and no symptoms of heart failure; however, these patients have the chronic risk of organ rejection and lifelong immunosuppressive therapy (see Chapter 443.1). The combination of donor shortage and improved results with standard surgical and hybrid procedures has caused most centers to stop recommending transplantation except when associated lesions make the Norwood operation an exceptionally high-risk procedure, or for patients who develop poor ventricular function at some time after the standard surgical approach.

There are some subgroups of patients with hypoplastic left-heart syndrome that may be at increased surgical risk, particularly those with mitral stenosis plus aortic atresia. These data need confirmation in larger studies, and alternative approaches to remain to be developed.

PREVENTION

Serial fetal echocardiographic studies demonstrate that in some fetuses, hypoplastic left-heart syndrome may be a progressive lesion, beginning with simple valvar aortic stenosis in midgestation. The decreased flow through the stenotic aortic valve reduces flow through the left ventricle during development, resulting in gradual ventricular chamber hypoplasia. The potential for preventing this hypoplasia has been demonstrated by performing in utero aortic balloon valvuloplasty in midgestation fetuses (Fig. 431-13). Early results are encouraging, although even if the aortic valve is successfully opened, adequate ventricular growth occurs in only about 30% of patients. At present, this procedure is regarded as experimental.

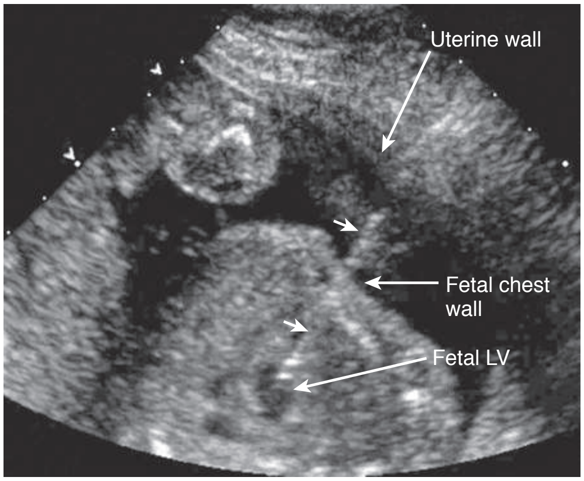

Figure 431-13 **Fetal treatment of critical aortic stenosis to prevent development of hypoplastic left-heart syndrome.** Fetal ultrasound showing insertion of a needle *(arrowheads)* via the maternal abdominal wall, through the uterus and the fetal chest wall, and into the fetal left ventricle (LV). A balloon catheter is next inserted via the needle into the left ventricular chamber and across the stenotic aortic valve. The balloon is inflated to dilate the valve, the catheter and needle are removed. *(Courtesy of Dr. Stanton Perry, Stanford University, Stanford, CA.)*

431.11 Abnormal Positions of the Heart and the Heterotaxy Syndromes (Asplenia, Polysplenia)

Daniel Bernstein

Classification and diagnosis of abnormal cardiac position are best performed via a segmental approach, with the position of the viscera and atria defined first, and then the ventricles, followed by the great vessels (Fig. 431-14). Determination of **visceroatrial situs** can be made by radiography demonstration of the position of the abdominal organs and the tracheal bifurcation for recognition of the right and left bronchi and by echocardiography. The atrial situs is usually similar to the situs of the viscera and lungs. In **situs solitus**, the viscera are in their normal positions (stomach and spleen on the left, liver on the right), the

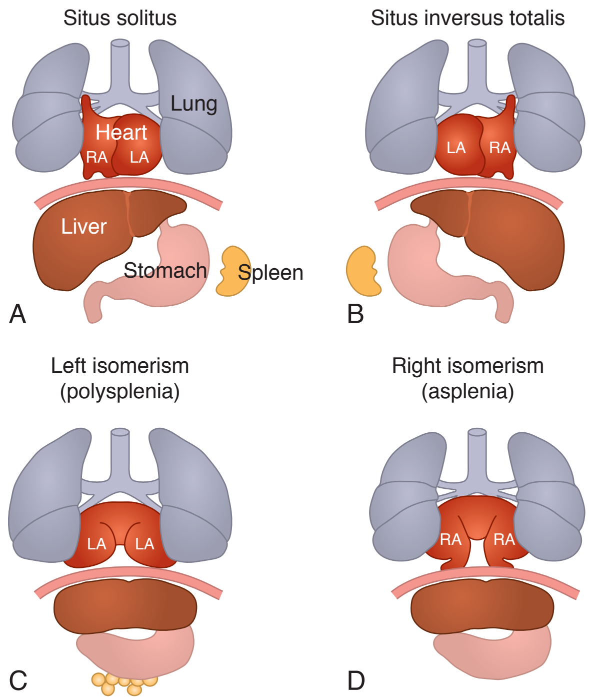

Figure 431-14 Variations in thoracoabdominal situs in congenital heart disease. A, *Situs solitus:* on the right side there is a three-lobed lung, a right atrium (with superior and inferior vena cava entering), and the liver; on the left side there is a two-lobed lung, a left atrium (with pulmonary veins entering), the stomach and the spleen. B, *Situs inversus totalis:* all of the structures are mirror image reversed: on the right side there is a two-lobed lung, a left atrium, the stomach, and the spleen; on the left side there is a three-lobed lung, a right atrium, and the liver. C, *Left isomerism (polysplenia):* there are two left sides: on the right side there is a two-lobed lung and a structure that resembles the left atrium; on the left side there is also a two-lobed lung and a structure that resembles the left atrium; there is usually a midline liver and stomach, and multiple small spleens. D, *Right isomerism (asplenia):* there are two right sides: on the right side there is a three-lobed lung and a structure that resembles the right atrium; on the left side there is also a three-lobed lung and a structure that resembles the right atrium; there is usually a midline liver and stomach, and absent spleen. *(Modified from Fliegauf M, Benzing T, Omran H: When cilia go bad: cilia defects and ciliopathies.* Nat Rev Mol Cell Biol *8:880-893, 2007. The ground-glass appearance of the lungs was caused by total anomalous pulmonary venous connection with obstruction. *(From Perloff JK, Marelli AJ:* Perloff's clinical recognition of congenital heart disease, *ed 6, Philadelphia, 2012, Elsevier/Saunders, Fig. 3-31, p 32.)*

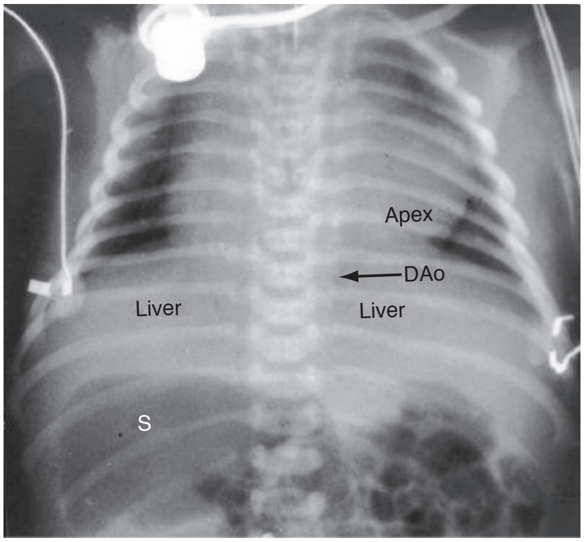

Figure 431-16 X-ray from a polysplenic female neonate with left isomerism. The liver is transverse, the apex is on the left, the stomach *(S)* is on the right, and the descending aorta *(DAo)* is on the left. This opposite-sided arrangement tends to occur in left isomerism. *(From Perloff JK, Marelli AJ:* Perloff's clinical recognition of congenital heart disease, *ed 6, Philadelphia, 2012, Elsevier/Saunders, Fig. 3-40, p 38.)*

3-lobed right lung is on the right, and the 2-lobed left lung on the left; the right atrium is on the right, and the left atrium is on the left. When the abdominal organs and lung lobation are reversed, an arrangement known as **situs inversus** occur, the left atrium is on the right and the right atrium on the left. If the visceroatrial situs cannot be readily determined, a condition known as **situs indeterminus** or **heterotaxia** exists. The 2 major variations are (1) **asplenia syndrome** (right isomerism or bilateral right-sidedness), which is associated with a centrally located liver, absent spleen, and 2 morphologic right lungs (Fig. 431-15); and (2) **polysplenia syndrome** (left isomerism or bilateral left-sidedness), which is associated with multiple small spleens, absence of the intrahepatic portion of the inferior vena cava, and 2 morphologic left lungs (Fig. 431-16). The heterotaxia syndromes are usually associated with severe congenital heart lesions: ASD, VSD, atrioventricular septal defect, hypoplasia of 1 of the ventricles, pulmonary stenosis or atresia, and anomalous systemic venous or pulmonary venous return (Table 431-2).

The next segment is localization of the ventricles, which depends on the direction of development of the embryonic cardiac loop. Initial protrusion of the loop to the right (d-loop) carries the future right ventricle anteriorly and to the right, whereas the left ventricle remains posterior and on the left. With situs solitus, a d-loop yields normal atrioventricular connections (right atrium connecting to the right ventricle, left atrium to the left ventricle). Protrusion of the loop to the left (l-loop) carries the future right ventricle to the left and the left ventricle to the right. In this case, in the presence of situs solitus, the right atrium connects with the left ventricle and the left atrium with the right ventricle **(ventricular inversion).**

The final segment is that of the great vessels. With each type of cardiac loop, the ventricular-arterial relationships may be regarded as either normal (right ventricle to the pulmonary artery, left ventricle to the aorta) or transposed (right ventricle to the aorta, left ventricle to the pulmonary artery). A further classification can be based on the position of the aorta (normally to the right and posterior) relative to the pulmonary artery. In transposition, the aorta is usually anterior and either to the right of the pulmonary artery **(d-transposition)** or to the left **(l-transposition).** These segmental relationships can usually be determined by echocardiographic studies demonstrating both atrioventricular and ventriculoarterial relationships. The clinical manifestations of these syndromes of abnormal cardiac position are determined primarily by their associated cardiovascular anomalies.

Dextrocardia occurs when the heart is in the right side of the chest; **levocardia** (the normal situation) is present when the heart is in the left side of the chest. Dextrocardia without associated situs inversus and levocardia in the presence of situs inversus are most often complicated by other severe cardiac malformations. Surveys of older children and adults indicate that dextrocardia with situs inversus and normally related great arteries ("mirror-image" dextrocardia) is often associated with a functionally normal heart, although congenital heart disease of a less severe nature is common.

Anatomic or functional abnormalities of the lungs, diaphragm, and thoracic cage may result in displacement of the heart to the right **(dextroposition).** In this case, however, the cardiac apex is pointed

Table 431-2	Comparison of Cardiosplenic Heterotaxy Syndromes	
FEATURE	**ASPLENIA (RIGHT ISOMERISM)**	**POLYSPLENIA (LEFT ISOMERISM)**

Dextrocardia (%)	30-40	30-40
Pulmonary blood flow	Decreased (usually)	Increased (usually)
Severe cyanosis	Yes	No
Transposition of great arteries (%)	60-75	15
Total anomalous pulmonary venous return (%)	70-80	Rare
Common atrioventricular valve (%)	80-90	20-40
Single ventricle (%)	40-50	10-15
Absent inferior vena cava with azygos continuation	No	Characteristic
Bilateral superior vena cava	Yes	Yes
Other common defects	PA, PS	Partial anomalous pulmonary venous return, ventricular septal defect, double-outlet right ventricle
Risk of pneumococcal sepsis	Yes	Yes
Howell-Jolly and Heinz bodies, pitted erythrocytes	Yes	No
Risk of nosocomial infection	Yes	Yes
Absent gallbladder; biliary atresia	No	Yes

PA, pulmonary atresia; PS, pulmonary stenosis.

normally to the left. This anatomic position is less often associated with congenital heart lesions, although hypoplasia of a lung may be accompanied by anomalous pulmonary venous return from that lung (**scimitar syndrome** [see Chapter 426.4]).

The electrocardiogram is difficult to interpret in the presence of lesions with discordant atrial, ventricular, and great vessel anatomy. Diagnosis usually requires detailed echocardiographic and sometimes MRI, CT, or cardiac catheterization studies. The prognosis and treatment of patients with 1 of the cardiac positional anomalies are determined by the underlying defects and are covered in their respective chapters. Asplenia increases the risk of serious infections such as bacterial sepsis and thus requires daily antibiotic prophylaxis. Patients with polysplenia frequently have poor splenic function and may also require prophylaxis against pneumococcal sepsis. Patients with heterotaxia are also at increased risk of intestinal malrotation and volvulus.

Chapter 432

Other Congenital Heart and Vascular Malformations

432.1 Anomalies of the Aortic Arch

Daniel Bernstein

RIGHT AORTIC ARCH

In this abnormality, the aorta curves to the right and, if it descends on the right side of the vertebral column, is usually associated with other cardiac malformations. It is found in 20% of cases of tetralogy of Fallot and is also common in truncus arteriosus. A right aortic arch without other cardiac anomalies is not associated with symptoms. It can often be visualized on the chest roentgenogram. The trachea is deviated slightly to the left of the midline rather than to the right, as in the presence of a normal left arch. On a barium esophagogram, the esophagus is indented on its right border at the level of the aortic arch.

VASCULAR RINGS

Congenital abnormalities of the aortic arch and its major branches result in the formation of vascular rings around the trachea and esophagus with varying degrees of compression (Table 432-1). The origin of these lesions can best be appreciated by reviewing the embryology of the aortic arch (see Fig. 420-1 in Chapter 420). The most common anomalies include (1) double aortic arch (Fig. 432-1*A*), (2) right aortic arch with a left ligamentum arteriosum, (3) anomalous innominate artery arising farther to the left on the arch than usual, (4) anomalous left carotid artery arising farther to the right than usual and passing anterior to the trachea, and (5) anomalous left pulmonary artery (vascular sling). In the latter anomaly, the abnormal vessel arises from an elongated main pulmonary artery or from the right pulmonary artery. It courses between and compresses the trachea and the esophagus. Associated congenital heart disease may be present in 5-50% of patients, depending on the vascular anomaly.

Clinical Manifestations

If the vascular ring produces compression of the trachea and esophagus, symptoms are frequently present during infancy. Chronic wheezing is exacerbated by crying, feeding, and flexion of the neck. Extension of the neck tends to relieve the noisy respiration. Vomiting may also be a component. Affected infants may have a brassy cough, pneumonia, or rarely, sudden death from aspiration.

Diagnosis

Standard roentgenographic examination is not usually helpful. In the past, performing a barium esophagogram was the standard method of diagnosis (Fig. 432-2), replaced today by echocardiography in combination with either MRI or CT. Cardiac catheterization is reserved for cases with associated anomalies or in rare cases where these other modalities are not diagnostic. Bronchoscopy may be helpful in more severe cases to determine the extent of airway narrowing.

Treatment

Surgery is advised for symptomatic patients who have evidence of tracheal compression. The anterior vessel is usually divided in patients with a double aortic arch (see Fig. 432-1*B*). Compression produced by a right aortic arch and left ligamentum arteriosum is relieved by division of the latter. Anomalous innominate or carotid arteries cannot be

divided; attaching the adventitia of these vessels to the sternum usually relieves the tracheal compression. An anomalous left pulmonary artery is corrected by division at its origin and re-anastomosis to the main pulmonary artery after it has been brought in front of the trachea. Severe tracheomalacia, if present, may require reconstruction of the trachea as well.

Bibliography is available at Expert Consult.

432.2 Anomalous Origin of the Coronary Arteries

Daniel Bernstein

Table 432-2 provides a classification system for coronary artery anomalies. Many of these anomalies are isolated. Nonetheless congenital anomalies of the coronary arteries may also be seen in patients with congenital heart disease (tetralogy of Fallot, transposition of the great arteries, congenitally corrected transposition of the great arteries, single ventricle, tricuspid atresia, truncus arteriosus, quadricuspid or bicuspid aortic valves, double-outlet ventricle). In addition, acquired lesions of the coronary arteries caused by existing congenital heart disease may develop as a consequence of hypertension or alterations in blood flow; congenital heart diseases include coarctation of the aorta, supravalvular aortic stenosis, aortic regurgitation, pulmonary atresia with intact ventricular septum, hypoplastic left-heart syndrome, and coronary ectasia secondary to cyanotic heart disease.

ANOMALOUS ORIGIN OF THE LEFT CORONARY ARTERY FROM THE PULMONARY ARTERY

In anomalous origin of the left coronary artery from the pulmonary artery, the blood supply to the left ventricular myocardium is severely compromised. Soon after birth, as pulmonary arterial pressure falls, perfusion pressure to the left coronary artery becomes inadequate; myocardial ischemia, infarction, and fibrosis result. In some cases, interarterial collateral anastomoses develop between the right and left coronary arteries. Blood flow in the left coronary artery is then reversed, and it empties into the pulmonary artery, a condition known as the “myocardial steal” syndrome. The left ventricle becomes dilated, and its performance is decreased. Mitral insufficiency is a frequent complication secondary to a dilated valve ring or infarction of a papillary muscle. Localized aneurysms may also develop in the left ventricular free wall. Occasional patients have adequate myocardial blood flow during childhood and, later in life, a continuous murmur and a small left-to-right shunt via the dilated coronary system (aorta to right coronary to left coronary to pulmonary artery).

Table 432-2 Congenital Anomalies of Coronary Arteries Unassociated with Congenital Heart Disease

Anomalous Aortic Origin
• Eccentric ostium within an aortic sinus
• Ectopic ostium above an aortic sinus
• Conus artery from the right aortic sinus
• Circumflex coronary artery from the right aortic sinus or from the right coronary artery
• Origin of left anterior descending and circumflex coronary arteries from separate ostia in the left aortic sinus (absence of left main coronary artery)
• Atresia of the left main coronary artery
• Origin of the left anterior descending coronary artery from the right aortic sinus or from the right coronary artery
• Origin of the right coronary artery from the left aortic sinus, from posterior aortic sinus, or from left coronary artery
• Origin of a single coronary artery from the right or left aortic sinus
• Anomalous origin from a noncardiac systemic artery
Anomalous Aortic Origin with Anomalous Proximal Course
• Acute proximal angulation
• Ectopic right coronary artery passing between aorta and pulmonary trunk
• Ectopic left main coronary artery:
• Between aorta and pulmonary trunk
• Anterior to the pulmonary trunk
• Posterior to the aorta
• Within the ventricular septum (intramyocardial)
• Ectopic left anterior descending coronary artery that is anterior, posterior, or between the aorta and pulmonary trunk
Anomalous Origin of a Coronary Artery from the Pulmonary Trunk
• Left main coronary artery
• Left anterior descending coronary artery
• Right coronary artery
• Both right and left coronary arteries
• Circumflex coronary artery
• Accessory coronary artery

From Perloff JK, Marelli J: Perloff's clinical recognition of congenital heart disease, *ed 6, Philadelphia, 2012, Elsevier/Saunders, Table 32-3, p. 532.*

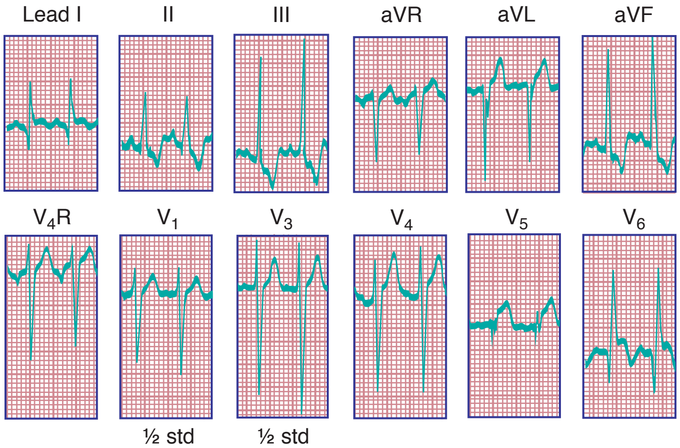

Figure 432-3 **Electrocardiogram of a 3 mo old child with anomalous origin of the left coronary artery from the pulmonary artery.** Lateral myocardial infarction is present as evidenced by abnormally large and wide Q waves in leads I, V_5, and V_6; an elevated ST segment in V_5 and V_6; and inversion of TV_6.

Clinical Manifestations

Evidence of heart failure becomes apparent within the 1st few mo of life, and may be exacerbated by respiratory infection. Recurrent attacks of discomfort, restlessness, irritability, sweating, dyspnea, and pallor occur and probably represent **angina pectoris**. Cardiac enlargement is moderate to massive. A gallop rhythm is common. Murmurs may be of the nonspecific ejection type or may be holosystolic due to mitral insufficiency. Older patients with abundant intercoronary anastomoses may have continuous murmurs and minimal left ventricular dysfunction. During adolescence, they may experience angina during exercise. Rare patients with an anomalous right coronary artery may also have such clinical findings.

Diagnosis

Roentgenographic examination confirms the cardiomegaly. The electrocardiogram resembles the pattern described in lateral wall myocardial infarction in adults. A QR pattern followed by inverted T waves is seen in leads I and aVL. The left ventricular surface leads (V_5 and V_6) may also show deep Q waves and exhibit elevated ST segments and inverted T waves (Fig. 432-3). Two-dimensional echocardiography can usually suggest the diagnosis; however, echocardiography is not always reliable in diagnosing this condition. On 2-dimensional imaging alone, the left coronary artery may appear as though it is arising from the aorta. Color Doppler ultrasound examination has improved the accuracy of diagnosis of this lesion, demonstrating the presence of retrograde flow in the left coronary artery. CT or MRI may be helpful in confirming the origin of the coronary arteries. Cardiac catheterization is diagnostic; aortography shows immediate opacification of the right coronary artery only. This vessel is large and tortuous. After filling of the intercoronary anastomoses, the left coronary artery is opacified, and contrast can be seen to enter the pulmonary artery. Pulmonary arteriography may also opacify the origin of the anomalous left coronary artery. Selective left ventriculography usually demonstrates a dilated left ventricle that empties poorly and mitral regurgitation.

Treatment and Prognosis

Untreated, death often occurs from heart failure within the 1st 6 mo of life. Those who survive generally have abundant intercoronary collateral anastomoses. Medical management includes standard therapy for heart failure (diuretics, angiotensin-converting enzyme inhibitors) and for controlling ischemia (nitrates, β-blocking agents).

Surgical treatment consists of detaching the anomalous coronary artery from the pulmonary artery and anastomosing it to the aorta to establish normal myocardial perfusion. A seriously ill infant with a tiny left coronary artery may present a difficult technical problem. In patients who have already sustained a significant myocardial infarction, cardiac transplantation may be the best option (see Chapter 441.1).

ANOMALOUS ORIGIN OF THE RIGHT CORONARY ARTERY FROM THE PULMONARY ARTERY

Anomalous origin of the right coronary artery from the pulmonary artery is rarely manifested in infancy or early childhood. The left coronary artery is enlarged, whereas the right is thin-walled and mildly enlarged. In early infancy, perfusion of the right coronary artery is from the pulmonary artery, whereas later, perfusion is from collaterals of the left coronary vessels. Angina and sudden death can occur in adolescence or adulthood. When recognized, this anomaly should be repaired by re-anastomosis of the right coronary artery to the aorta.

ECTOPIC ORIGIN OF THE CORONARY ARTERY FROM THE AORTA WITH ABERRANT PROXIMAL COURSE

In ectopic origin of the coronary artery from the aorta with an aberrant proximal course, the aberrant artery may be a left, right, or major branch coronary artery. The site of origin may be the wrong sinus of Valsalva or a proximal coronary artery. The ostium may be hypoplastic, slitlike, or of normal caliber. The aberrant vessel may pass anteriorly, posteriorly, or between the aorta and right ventricular outflow tract; it may tunnel in the conal or interventricular septal tissue. Obstruction

resulting from hypoplasia of the ostia, tunneling between the aorta and right ventricular outflow tract or interventricular septum, and acute angulation produces myocardial infarction. Unobstructed vessels produce no symptoms. Patients with this extremely rare abnormality are often initially seen with severe myocardial infarction, ventricular arrhythmias, angina pectoris, or syncope; sudden death may occur, especially in young athletes.

Diagnostic modalities include an electrocardiogram, stress testing, 2-dimensional echocardiography, CT or MRI, radionuclide perfusion scan, and cardiac catheterization with selective coronary angiography.

Treatment is indicated for obstructed vessels and consists of aortoplasty with reanastomosis of the aberrant vessel or, occasionally, coronary artery bypass grafting. The management of asymptomatic infants with these forms of ectopic coronary origin remains controversial.

432.3 Pulmonary Arteriovenous Fistula

Daniel Bernstein

Fistulous vascular communications in the lungs may be large and localized or multiple, scattered, and small. The most common form of this unusual condition is the **Osler-Weber-Rendu syndrome** (hereditary hemorrhagic telangiectasia type I), which is also associated with angiomas of the nasal and buccal mucous membranes, gastrointestinal tract, or liver. Mutations in the endoglin gene, a cell surface component of the transforming growth factor-β receptor complex causes this syndrome. The usual communication is between the pulmonary artery and pulmonary vein; direct communication between the pulmonary artery and left atrium is extremely rare. Desaturated blood in the pulmonary artery is shunted through the fistula into the pulmonary vein, thus bypassing the lungs, and then enters the left side of the heart resulting in systemic arterial desaturation and, sometimes, clinically detectable cyanosis. The shunt across the fistula is at low pressure and resistance, so pulmonary arterial pressure is normal; cardiomegaly and heart failure are not present.

The clinical manifestations depend on the magnitude of the shunt. Large fistulas are associated with dyspnea, cyanosis, clubbing, a continuous murmur, and polycythemia. Hemoptysis is rare, but when it occurs, it may be massive. Features of the Osler-Weber-Rendu syndrome are seen in ≈50% of patients (or other family members) and include recurrent epistaxis and gastrointestinal tract bleeding. Transitory dizziness, diplopia, aphasia, motor weakness, or convulsions may result from cerebral thrombosis, abscess, or paradoxical emboli. Soft systolic or continuous murmurs may be audible over the site of the fistula. The electrocardiogram is normal. Roentgenographic examination of the chest may show opacities produced by large fistulas; multiple small fistulas may be visualized by fluoroscopy (as abnormal pulsations), MRI, or CT. Selective pulmonary arteriography demonstrates the site, extent, and distribution of the fistulas.

Treatment consisting of excision of solitary or localized lesions by lobectomy or wedge resection results in complete disappearance of symptoms. In most instances, fistulas are so widespread that surgery is not possible. Any direct communication between the pulmonary artery and the left atrium can be obliterated.

Patients who have undergone a **Glenn cavopulmonary** anastomosis for cyanotic congenital heart disease (see Chapter 430.4) are also at risk for the development of pulmonary arteriovenous malformations. In these patients, the arteriovenous malformations are usually multiple and the risk increases over time after the Glenn procedure. These malformations rarely occur after the heart disease is fully palliated by completion of the Fontan operation. This finding suggests that the pulmonary circulation requires an as yet undetermined hepatic factor to suppress the development of arteriovenous malformations. The hallmark of the development of these malformations is a decrease in the patient's oxygen saturation. The diagnosis can often be made with contrast echocardiography; cardiac catheterization is the definitive test. Completion of the Fontan circuit, so that inferior vena cava blood flow (containing hepatic venous drainage) is routed through the lungs, usually results in improvement or resolution of the malformations.

Bibliography is available at Expert Consult.

432.4 Ectopia Cordis

Daniel Bernstein

In the most common thoracic form of ectopia cordis, the sternum is split and the heart protrudes outside the chest. In other forms, the heart protrudes through the diaphragm into the abdominal cavity or may be situated in the neck. Associated intracardiac anomalies are common. **Pentalogy of Cantrell** consists of ectopia cordis, midline supraumbilical abdominal defect, deficiency of the anterior diaphragm, defect of the lower sternum, and an intracardiac defect (either a ventricular septal defect, tetralogy of Fallot, or diverticulum of the left ventricle). Death may occur early in life, usually from infection, cardiac failure, or hypoxemia. Surgical therapy for neonates without overwhelmingly severe cardiac anomalies consists of covering the heart with skin without compromising venous return or ventricular ejection. Repair or palliation of associated defects is also necessary.

432.5 Diverticulum of the Left Ventricle

Daniel Bernstein

Left ventricular diverticulum is a rare anomaly, where the diverticulum protrudes into the epigastrium. The lesion may be isolated or associated with complex cardiovascular anomalies. A pulsating mass is usually visible and palpable in the epigastrium. Systolic or systolic-diastolic murmurs produced by blood flow into and out of the diverticulum may be audible over the lower part of the sternum and the mass. The electrocardiogram shows a pattern of complete or incomplete left bundle branch block. Roentgenograms of the chest may or may not show the mass. Associated abnormalities include defects of the sternum, abdominal wall, diaphragm, and pericardium (see earlier). Surgical treatment of the diverticulum and associated cardiac defects can be performed in selected cases. Occasionally, a diverticulum may be small and not associated with clinical signs or symptoms. These small diverticula are diagnosed at the time of echocardiographic examination for other indications.

Chapter 433
Pulmonary Hypertension

433.1 Primary Pulmonary Hypertension

Daniel Bernstein

PATHOPHYSIOLOGY

Primary pulmonary hypertension is characterized by pulmonary vascular obstructive disease and right-sided heart failure. It occurs at any age, although in pediatric patients the mean age at diagnosis is 7-10 yr. In patients with idiopathic or familial disease, females outnumber males 1.7 : 1; in other patients, both genders are represented equally. Some patients have evidence of either an immunologic disorder or a hypercoagulable state. Mutations in the gene for bone morphogenetic protein receptor-2 (*BMPR-2*, a member of the transforming growth factor-β receptor family) on chromosome 2q33 have been identified in 70% of patients with familial primary pulmonary hypertension (known as *PPH1*) and in 10-20% with idiopathic sporadic pulmonary

hypertension. Other potential disease causing genes include *PPH2*, *ALK1*, *ENG*, *SMAD9*, *CAV1*, and *KCNK3*, which causes a channelopathy in familial and sporadic cases of primary pulmonary hypertension. Viral infection, such as with the vasculotropic human herpesvirus 8, has been suggested as a trigger factor in many patients. Diet pills, particularly fenfluramine, have also been implicated. Pulmonary hypertension is a common complication of sickle cell anemia and other hemolytic anemias. Pulmonary hypertension is associated with precapillary obstruction of the pulmonary vascular bed as a result of hyperplasia of the muscular and elastic tissues and a thickened intima of the small pulmonary arteries and arterioles (Fig. 433-1). Secondary atherosclerotic changes may be found in the larger pulmonary arteries as well. In children, **pulmonary venoocclusive disease** may account for some cases of primary pulmonary hypertension. Before a diagnosis of primary pulmonary hypertension can be made, other causes of elevated pulmonary arterial pressure must be eliminated (chronic pulmonary parenchymal disease, persistent obstruction of the upper airway, congenital cardiac malformations, recurrent pulmonary emboli, alveolar capillary dysplasia, liver disease, autoimmune disease,

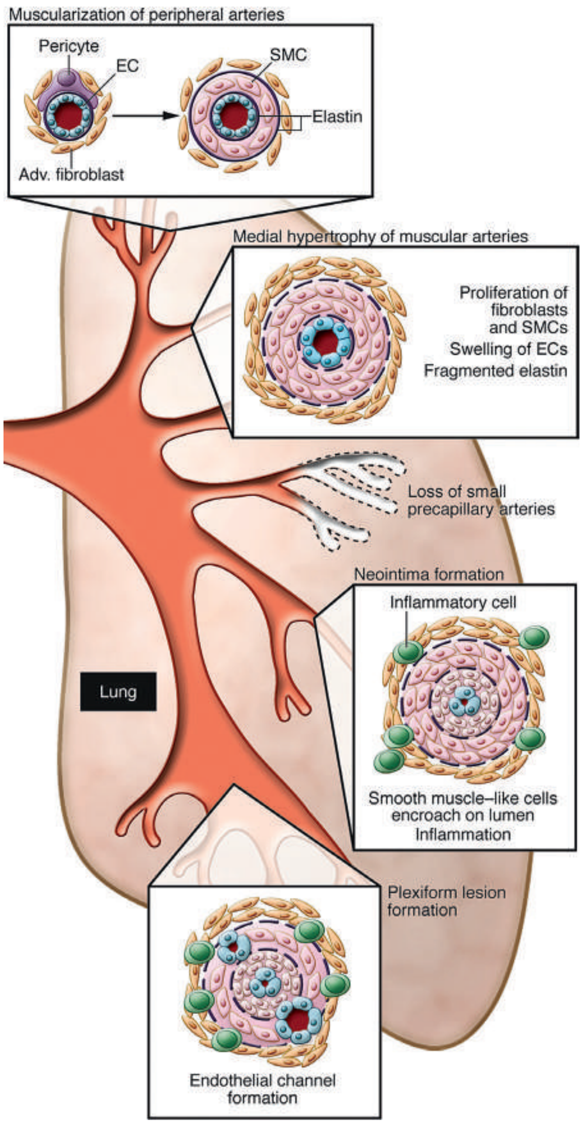

Figure 433-1 Vascular abnormalities associated with pulmonary arterial hypertension: abnormal muscularization of distal and medial precapillary arteries, loss of precapillary arteries, thickening of large pulmonary arterioles, and neointimal formation that is occlusive in vessels <500-100 μM and in plexiform lesions therein. *(From Rabinovitch M: Molecular pathogenesis of pulmonary arterial hypertension.* J Clin Invest *122:4306-4313, 2012, Fig. 1.)*

and moyamoya disease). Table 433-1 provides a classification system. Idiopathic or familial disease is the most common in pediatric patients (~55%), followed by pulmonary hypertension secondary to congenital heart disease (~35%) and chronic respiratory disorders (~15%).

Pulmonary hypertension places an afterload burden on the right ventricle, which results in right ventricular hypertrophy. Dilation of the pulmonary artery is present, and pulmonary valve insufficiency may occur. In the later stages of the disease, the right ventricle dilates, tricuspid insufficiency develops, and cardiac output is decreased. Arrhythmias, syncope, and sudden death are common.

CLINICAL MANIFESTATIONS

The predominant symptoms include exercise intolerance (dyspnea) and fatigability; occasionally, precordial chest pain, dizziness, or headaches are noted. Syncope may be noted in ~30% of pediatric patients. Peripheral cyanosis may be present, especially during exercise or in patients with a patent foramen ovale through which blood can shunt from right to left; in the late stages of disease, patients may have cold extremities and a gray appearance associated with low cardiac output. Arterial oxygen saturation is usually normal unless there is an associated intracardiac shunt. If right-sided heart failure has supervened, jugular venous pressure is elevated, and hepatomegaly and edema are present. Jugular venous *a* waves are present, and in those with functional tricuspid insufficiency, a conspicuous jugular *cv* wave and systolic hepatic pulsations are manifested. The heart is moderately enlarged, and a right ventricular heave can be noted. The 1st heart sound is often followed

Table 433-1	Revised World Health Organization Classification of Pulmonary Hypertension

1. Pulmonary arterial hypertension (PAH)
   1.1. Idiopathic (IPAH)
   1.2. Familial (FPAH)
   1.3. Associated with (APAH):
      1.3.1. Connective tissue disorder
      1.3.2. Congenital systemic-to-pulmonary shunts
      1.3.3. Portal hypertension
      1.3.4. HIV infection
      1.3.5. Drugs and toxins
      1.3.6. Other (thyroid disorders, glycogen storage disease, Gaucher disease, hereditary hemorrhagic telangiectasia, hemoglobinopathies, chronic myeloproliferative disorders, splenectomy)
   1.4. Associated with significant venous or capillary involvement
      1.4.1. Pulmonary venoocclusive disease (PVOD)
      1.4.2. Pulmonary capillary hemangiomatosis (PCH)
   1.5. Persistent pulmonary hypertension of the newborn
2. Pulmonary hypertension with left-heart disease
   2.1. Left-sided atrial or ventricular heart disease
   2.2. Left-sided valvular heart disease
3. Pulmonary hypertension associated with lung diseases and/or hypoxemia
   3.1. Chronic obstructive pulmonary disease
   3.2. Interstitial lung disease
   3.3. Sleep disordered breathing
   3.4. Alveolar hypoventilation disorders
   3.5. Chronic exposure to high altitude
   3.6. Developmental abnormalities
4. Pulmonary hypertension due to chronic thrombotic and/or embolic disease (CTEPH)
   4.1. Thromboembolic obstruction of proximal pulmonary arteries
   4.2. Thromboembolic obstruction of distal pulmonary arteries
   4.3. Nonthrombotic pulmonary embolism (tumor, parasites, foreign material)
5. Miscellaneous: sarcoidosis, histiocytosis X, lymphangiomatosis, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

From ACCF/AHA: 2009 Expert consensus document on pulmonary hypertension: a report of the American College of Cardiology Foundation Task Force on Expert Consensus Documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc; and the Pulmonary Hypertension Association, J Am Coll Cardiol *53:1573–1619, 2009.*

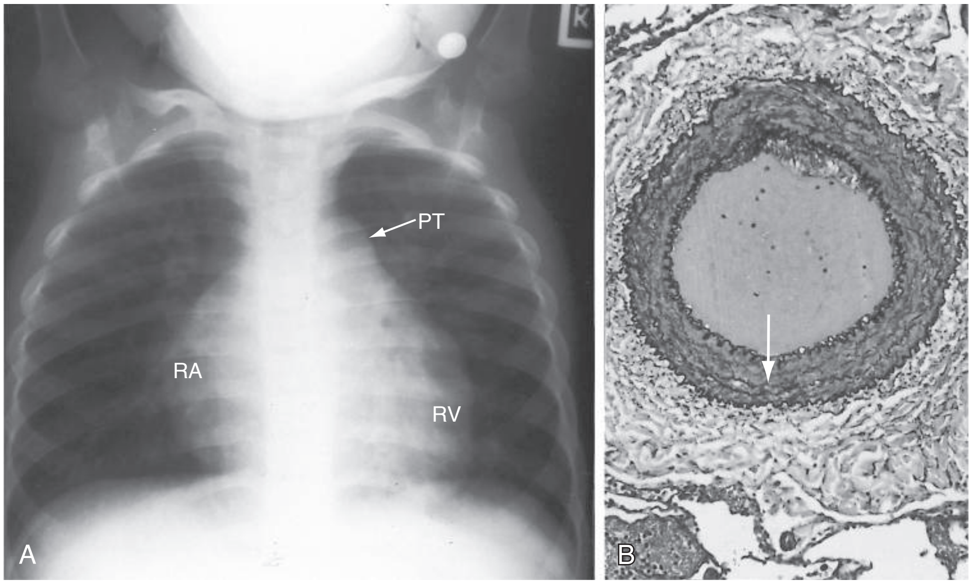

Figure 433-2 **A,** X-ray from a 3 yr old girl with primary pulmonary hypertension. Pulmonary vascularity is reduced. The pulmonary trunk (PT), right atrium (RA), and right ventricle (RV) are considerably enlarged. **B,** Histology of an intrapulmonary artery at necropsy shows medial hypertrophy (arrow). *(From Perloff JK, Marelli AJ:* Perloff's clinical recognition of congenital heart disease, *ed 6, Philadelphia, 2012, Elsevier/Saunders, Fig. 14-17, p. 207.)*

by an ejection click emanating from the dilated pulmonary artery. The 2nd heart sound is narrowly split, loud, and sometimes booming in quality; it is frequently palpable at the upper left sternal border. A presystolic gallop rhythm may be audible at the lower left sternal border. The systolic murmur is soft and short and is sometimes followed by a blowing decrescendo diastolic murmur caused by pulmonary insufficiency. In later stages, a holosystolic murmur of tricuspid insufficiency is appreciated at the lower left sternal border.

DIAGNOSIS

Chest radiographs reveal a prominent pulmonary artery and right ventricle (Fig. 433-2). The pulmonary vascularity in the hilar areas may be prominent, in contrast to the peripheral lung fields in which pulmonary markings are decreased. The electrocardiogram shows right ventricular hypertrophy, often with spiked P waves. Echocardiography is used to screen for any congenital cardiac malformations. Doppler evaluation of the tricuspid valve, if insufficiency is present, will allow estimation of the right ventricular (and hence pulmonary arterial) systolic pressure.

At cardiac catheterization, the presence of left-sided obstructive lesions (pulmonary venous stenosis, mitral stenosis, restrictive cardiomyopathy) that result in pulmonary venous hypertension can be evaluated (see Chapters 427.9, 431.7, and 439.3). The presence of pulmonary arterial hypertension with a normal pulmonary capillary wedge pressure is diagnostic of primary pulmonary hypertension. If the wedge pressure is elevated and left ventricular end-diastolic pressure is normal, obstruction at the level of the pulmonary veins, left atrium, or mitral valve should be suspected. If left ventricular end-diastolic pressure is also elevated, the diagnosis of restrictive cardiomyopathy should be entertained. The risks associated with cardiac catheterization are increased in severely ill patients with primary pulmonary hypertension.

PROGNOSIS AND TREATMENT

Primary pulmonary hypertension is progressive, and no cure is currently available. Some success has been reported with oral calcium channel blocking agents such as nifedipine in children who demonstrate pulmonary vasoreactivity when these agents are administered during catheterization. Continuous intravenous infusion of the arachidonic acid metabolite, prostacyclin (epoprostenol), provides relief as long as the infusion is continued. Despite the success of prostacyclin in reducing symptoms and improving quality of life, it slows but does not stop the progression of the disease. Treprostinil, a prostacyclin analog with a longer half-life has also been shown to be effective. Continuous administration of nitric oxide via nasal cannula, nebulized forms of prostacyclin (iloprost), and orally administered pulmonary vasodilators (bosentan, an antagonist of endothelin receptors; or sildenafil, a phosphodiesterase type 5 inhibitor) have been used with success in adults and in preliminary clinical studies in children (Table 433-2). Anticoagulation may be of value in patients with previous pulmonary thromboemboli; some of these patients may respond to balloon angioplasty of narrowed pulmonary artery segments. Riociguat, a soluble guanylate cyclase stimulator, with vasorelaxation, antiproliferation, and antifibrotic properties, has proven effective in adults with chronic thromboembolic or idiopathic pulmonary hypertension. Despite many advances, definitive therapy is still heart-lung or lung transplantation (see Chapter 443.2). In patients with severe pulmonary hypertension and low cardiac output, the terminal event is often sudden and related to a lethal arrhythmia. Patients with primary pulmonary hypertension diagnosed in infancy often have rapid progression and high mortality.

433.2 Pulmonary Vascular Disease (Eisenmenger Syndrome)

Daniel Bernstein

PATHOPHYSIOLOGY

The term ***Eisenmenger syndrome*** refers to patients with a ventricular septal defect in which blood is shunted partially or totally from right to left as a result of the development of pulmonary vascular disease. This physiologic abnormality can also occur with atrioventricular septal defect, ventricular septal defect, patent ductus arteriosus or any other communication between the aorta and pulmonary artery, and in many forms of complex congenital heart disease with unrestricted pulmonary blood flow. Pulmonary vascular disease with an isolated atrial septal defect can occur, but is less common and does not occur until late in adulthood.

In Eisenmenger syndrome, pulmonary vascular resistance after birth either remains high or, after having decreased during early infancy, rises thereafter because of increased shear stress on pulmonary arterioles. Factors playing a role in the rapidity of development of pulmonary vascular disease include increased pulmonary arterial pressure, increased pulmonary blood flow, and the presence of hypoxia or hypercapnia. Early

Table 433-2 Summary of Drugs Used to Treat Pulmonary Hypertension*

DRUG AND MECHANISM OF ACTION	DOSES USED IN PEDIATRIC STUDIES	COMMON SIDE EFFECTS
Epoprostenol (prostacyclin [PGI_2], a potent vasodilator; also inhibits platelet aggregation)	1 ng/kg/min initially. Increase based on clinical course and tolerance to 5-50 ng/kg/min. Some patients may require even higher doses. Must be given by continuous infusion that is not interrupted	Flushing, headache, nausea, diarrhea, hypotension, chest pain, jaw pain
Iloprost (synthetic analog of PGI_2)	2.5-5.0 µg 6-9 times daily (not more frequently than every 2 hr) via inhalation	Flushing, headache, diarrhea, hypotension, jaw pain, exacerbation of pulmonary symptoms (cough, wheezing)
Treprostinil (synthetic analog of PGI_2)	1 ng/kg/min initially. Target dose ranges from 20-80 ng/kg/min. Given either IV or SC via continuous infusion. Longer half-life than epoprostenol	Flushing, headache, diarrhea, hypotension, jaw pain. Pain at infusion site when given SC
Bosentan, ambrisentan, (endothelin receptor EtA and EtB antagonist)	2 mg/kg/dose bid. Use ½ dose for 1st mo and check for liver function test abnormalities prior to up-titrating	Flushing, headache, diarrhea, hypotension, fluid retention, exacerbation of heart failure, anemia, elevated liver function tests, palpitations
Sildenafil (inhibitor of cyclic guanosine monophosphate-specific phosphodiesterase 5)	1 mg/kg/dose given 3-4 times daily. Initial dosing should be ½ final target dose to evaluate for hypotension	Flushing, headache, diarrhea, myalgia, hypotension, priapism, visual disturbance (blue coloration)
Calcium channel blockers (amlodipine, diltiazem, nifedipine)	Previously widely used. Now indicated only for patients who show a strong response to nitric oxide during cardiac catheterization	Flushing, headache, edema, arrhythmia, headache, hypotension, rash, nausea, constipation, elevated liver function tests

*These medications should only be administered under the direction of a specialist in pulmonary hypertension.

in the course of disease, pulmonary hypertension (elevated pressure in the pulmonary arteries) is the result of markedly increased pulmonary blood flow (hyperkinetic pulmonary hypertension). This form of pulmonary hypertension decreases with the administration of pulmonary vasodilators such as nitric oxide, or oxygen, or both. With the development of Eisenmenger syndrome, pulmonary hypertension is the result of pulmonary vascular disease (obstructive pathologic changes in the pulmonary vessels). This form of pulmonary hypertension is usually only minimally responsive to pulmonary vasodilators or oxygen or not at all.

PATHOLOGY AND PATHOPHYSIOLOGY

The pathologic changes of Eisenmenger syndrome occur in the small pulmonary arterioles and muscular arteries (<300 µm) and are graded on the basis of histologic characteristics (Heath-Edwards classification): **Grade I** changes involve medial hypertrophy alone, **grade II** consists of medial hypertrophy and intimal hyperplasia, **grade III** involves near obliteration of the vessel lumen, **grade IV** includes arterial dilation, and **grades V and VI** include plexiform lesions, angiomatoid formation, and fibrinoid necrosis. Grades IV-VI indicate irreversible pulmonary vascular obstructive disease. Eisenmenger physiology is usually defined by an absolute elevation in pulmonary arterial resistance to greater than 12 Wood units (resistance units indexed to body surface area) or by a ratio of pulmonary to systemic vascular resistance of ≥1.0.

Pulmonary vascular disease occurs more rapidly in patients with trisomy 21 who have left-to-right shunts. It also complicates the natural history of patients with elevated pulmonary venous pressure secondary to mitral stenosis or left ventricular dysfunction, especially in those patients with restrictive cardiomyopathy (see Chapter 445.3). Pulmonary vascular disease can also occur in any patient with transmission of systemic pressure to the pulmonary circulation via a shunt at the interventricular or great vessel level, and in patients chronically exposed to low Po_2 (because of high altitude). Patients with cyanotic congenital heart lesions associated with unrestricted pulmonary blood flow are at particularly high risk.

CLINICAL MANIFESTATIONS

Symptoms do not usually develop until the 2nd or 3rd decade of life, although a more fulminant course may occur. Intracardiac or extracardiac communications that would normally shunt from left to right are converted to right-to-left shunting as pulmonary vascular resistance exceeds systemic vascular resistance. Cyanosis becomes apparent, and dyspnea, fatigue, and a tendency toward dysrhythmias begin to occur. In the late stages of the disease, heart failure, chest pain, headaches, syncope, and hemoptysis may be seen. Physical examination reveals a right ventricular heave and a narrowly split 2nd heart sound with a loud pulmonic component. Palpable pulmonary artery pulsation may be present at the left upper sternal border. A holosystolic murmur of tricuspid regurgitation may be audible along the left sternal border. An early decrescendo diastolic murmur of pulmonary insufficiency may also be heard along the left sternal border. The degree of cyanosis depends on the stage of the disease.

DIAGNOSIS

Roentgenographically, the heart varies in size from normal to greatly enlarged; the latter usually occurs late in the course of the disease. The main pulmonary artery is generally prominent, similar to primary pulmonary hypertension (see Fig. 433-2). The pulmonary vessels are enlarged in the hilar areas and taper rapidly in caliber in the peripheral branches. The right ventricle and atrium are prominent. The electrocardiogram shows marked right ventricular hypertrophy. The P wave may be tall and spiked. Cyanotic patients have various degrees of polycythemia that depend on the severity and duration of hypoxemia.

The echocardiogram shows a thick-walled right ventricle and demonstrates the underlying congenital heart lesion. Two-dimensional echocardiography assists in eliminating from consideration lesions such as obstructed pulmonary veins, supramitral membrane, mitral stenosis, and restrictive cardiomyopathy. Doppler studies demonstrate the direction of the intracardiac shunt and the presence of a typical hypertension waveform in the main pulmonary artery. Tricuspid and pulmonary regurgitation can be used in the Doppler examination to estimate pulmonary arterial systolic and diastolic pressures.

Cardiac catheterization usually shows a bidirectional shunt at the site of the defect. Systolic pressure is generally equal in the systemic and pulmonary circulations. Pulmonary capillary wedge pressure is normal unless a left-sided heart obstructive lesion or left ventricular failure is the cause of the pulmonary arterial hypertension. Arterial oxygen saturation is decreased depending on the magnitude of

the right-to-left shunt. The response to vasodilator therapy (oxygen, prostacyclin, nitric oxide) may identify patients with hyperdynamic pulmonary hypertension. Selective pulmonary artery injections may be necessary if pulmonary venous obstruction is suspected because of high wedge pressure and low left ventricular end-diastolic pressure.

TREATMENT

The best management for patients who are at risk for the development of late pulmonary vascular disease is prevention by early surgical elimination of large intracardiac or great vessel communications during infancy. Some patients may be missed because they have not shown early clinical manifestations. Rarely, pulmonary vascular resistance never decreases at birth in these infants, and therefore they never acquire enough left-to-right shunting to become clinically apparent. Such delayed recognition is a particular risk in patients with congenital heart disease who live at high altitude. It is also a risk in infants with trisomy 21, who have a propensity for earlier development of pulmonary vascular disease. Because of the high incidence of congenital heart disease associated with trisomy 21, routine echocardiography is recommended at the time of initial diagnosis, even in the absence of other clinical findings.

Medical treatment of Eisenmenger syndrome is primarily symptomatic. Many patients benefit substantially from either oral (calcium channel blocker, endothelin antagonist, phosphodiesterase inhibitors) or chronic intravenous (prostacyclin) therapy. Combined heart-lung or bilateral lung transplantation is the only surgical option for many of these patients (see Chapter 443.2).

Chapter **434**

General Principles of Treatment of Congenital Heart Disease

Daniel Bernstein

Most patients who have mild congenital heart disease require no treatment. The parents and child should be made aware that a normal life is expected and that no restriction of the child's activities is necessary. Overprotective parents may use the presence of a mild congenital heart lesion or even a functional heart murmur as a means to exert excessive control over their child's activities. Although fears may not be expressed overtly, the child may become anxious regarding early death or debilitation, especially when an adult member of the family acquires unrelated symptomatic heart disease. The family may have an unexpressed fear of sudden death, and the rarity of this manifestation should be emphasized in discussions directed at improving their understanding of the child's congenital heart defect. The difference between congenital heart disease and degenerative coronary disease in adults should be emphasized. General health maintenance, including a well-balanced, "heart-healthy" diet; aerobic exercise; and avoidance of smoking, should be encouraged.

Even patients with moderate to severe heart disease need not be restricted from all physical activity, although many will tend to limit their own activities. **Physical education** should be modified appropriately to the child's capacity to participate; the extent of such modification can often be guided by formal exercise testing. Although competitive sports for some patients may need to be discouraged, decisions are made on an individual basis. The influence of coach and peer pressure should be taken into account when recommending competitive versus noncompetitive athletics. Many cardiologists will also prohibit certain high-impact activities ("collision sports") such as tackle football or contact martial arts in patients with some forms of prior open heart surgery.

Routine immunizations should be given, with the inclusion of influenza vaccine during the appropriate season. Prophylaxis against the respiratory syncytial virus is recommended during respiratory syncytial virus season in young infants with unrepaired congenital heart disease and significant hemodynamic abnormalities. However, careful consideration for timing of administration of live-virus vaccination is required in patients who are potential candidates for heart or heart-lung transplantation.

Bacterial infections should be treated vigorously, but the presence of congenital heart disease is not an appropriate reason to use antibiotics indiscriminately. Prophylaxis against bacterial endocarditis should be carried out during dental procedures for appropriate patients. The American Heart Association has recently significantly revised these recommendations, with most patients no longer requiring routine prophylaxis (see Chapter 437). Endocarditis prophylaxis is generally no longer recommended for gastrointestinal or genitourinary procedures.

Cyanotic patients need to be monitored for noncardiac manifestations of oxygen deficiency (Table 434-1). Treatment of iron-deficiency anemia is important in cyanotic patients, who will show improved exercise tolerance and general well-being with adequate hemoglobin levels. These patients should also be carefully observed for excessive polycythemia. Cyanotic patients should avoid situations in which dehydration may occur, which leads to increased viscosity and increases the risk of stroke. Diuretics may need to be decreased or temporarily discontinued during episodes of acute gastroenteritis. High altitudes and sudden changes in the thermal environment should also be avoided. Phlebotomy with partial exchange transfusion is carried out only in symptomatic patients with severe **polycythemia** (usually those whose hematocrit is >65%).

Patients with moderate to severe forms of congenital heart disease or a history of rhythm disturbance should be carefully monitored during anesthesia for even routine surgical procedures. Consultation with an anesthesiologist experienced in the care of children with congenital heart disease is recommended. Women with nonrepaired severe congenital heart disease should be counseled on the risks associated with childbearing and on the use of contraceptives and tubal ligation. Pregnancy may be dangerous to both mother and fetus for patients with chronic cyanosis or pulmonary arterial hypertension. Women with mild to moderate heart disease and many of those who have had corrective surgery can have normal pregnancies, although those with residual hemodynamic derangements or with systemic right ventricles should be followed by a high-risk perinatologist and a cardiologist with expertise in caring for adults with congenital heart disease.

POSTOPERATIVE MANAGEMENT

After successful open heart surgery, the severity of the congenital heart defect, the age and condition (nutritional status) of the patient before surgery, the events in the operating room, and the quality of the postoperative care influence the patient's course. Intraoperative factors that influence survival and that should be noted when a patient returns from the operating room include the duration of cardiopulmonary bypass, the duration of aortic cross-clamping (the time during which the heart is not being perfused), and the duration of profound hypothermia (used in some newborns: the period during which the entire body is not being perfused).

Immediate postoperative care should be provided in an intensive care unit staffed by a team of physicians, nurses, and technicians experienced with the unique problems encountered after open heart surgery in childhood. In most major centers, this occurs in a dedicated pediatric cardiovascular intensive care unit. Preparation for postoperative monitoring begins in the operating room, where the anesthesiologist

Table 434-1 Extracardiac Complications of Cyanotic Congenital Heart Disease and Eisenmenger Physiology

PROBLEM	ETIOLOGY	THERAPY
Polycythemia	Persistent hypoxia	Phlebotomy
Relative anemia	Nutritional deficiency	Iron replacement
CNS abscess	Right-to-left shunting	Antibiotics, drainage
CNS thromboembolic stroke	Right-to-left shunting or polycythemia	Phlebotomy
Low-grade DIC, thrombocytopenia	Polycythemia	None for DIC unless bleeding, then phlebotomy
Hemoptysis	Pulmonary infarct, thrombosis, or rupture of pulmonary artery plexiform lesion	Embolization
Gum disease	Polycythemia, gingivitis, bleeding	Dental hygiene
Gout	Polycythemia, diuretic agent	Allopurinol
Arthritis, clubbing	Hypoxic arthropathy	None
Pregnancy complications: abortion, fetal growth retardation, prematurity increase, maternal illness	Poor placental perfusion, poor ability to increase cardiac output	Bed rest, pregnancy prevention counseling
Infections	Associated asplenia, DiGeorge syndrome, endocarditis	Antibiotics
	Fatal RSV pneumonia with pulmonary hypertension	Ribavirin; RSV immunoglobulin (prevention)
Failure to thrive	Increased oxygen consumption, decreased nutrient intake	Treat heart failure; correct defect early; increase caloric intake
Protein-losing enteropathy	S/P Fontan; high right-sided pressures	Oral budesonide or sildenafil
Chylothorax	Injury to thoracic duct	Medium chain triglyceride diet Octreotide Surgical ligation of thoracic duct
Psychosocial adjustment	Limited activity, cyanotic appearance, chronic disease, multiple hospitalizations	Counseling

CNS, central nervous system; DIC, disseminated intravascular coagulation; RSV, respiratory syncytial virus; S/P, status post (after).

or surgeon places an arterial catheter to allow direct arterial pressure measurements and arterial sampling for blood gas determination. A central venous catheter is also placed for measuring central venous pressure and for infusions of cardioactive medications. In more complex cases, right or left atrial or pulmonary artery catheters may be inserted directly into these cardiac structures and used for pressure monitoring purposes. Temporary pacing wires are placed on the atrium or ventricle, or both, in case temporary postoperative heart block occurs. Transcutaneous oximetry provides for continuous monitoring of arterial oxygen saturation. Near-infrared spectroscopy has been used to monitor cerebral and other end-organ perfusion in the perioperative period.

Functional failure of 1 organ system may cause profound physiologic and biochemical changes in another. Respiratory insufficiency, for example, leads to hypoxia, hypercapnia, and acidosis, which, in turn, compromise cardiac, vascular, and renal function. The latter problems cannot be managed successfully until adequate ventilation is reestablished. Thus, it is essential that the primary source of each postoperative problem be identified and treated.

Respiratory failure is a serious postoperative complication encountered after open heart surgery. Cardiopulmonary bypass carried out in the presence of pulmonary congestion results in decreased lung compliance, copious tracheal and bronchial secretions, atelectasis, and increased breathing effort. Because fatigue and, subsequently, hypoventilation and acidosis may rapidly ensue, mechanical positive pressure endotracheal ventilation is usually continued after open heart surgery for a minimum of several hours in relatively stable patients and for up to 2-3 days or longer in severely ill patients, especially infants. Patients with certain congenital heart lesions, particularly those with DiGeorge syndrome, may also have airway abnormalities (micrognathia, tracheomalacia, bronchomalacia) that can make both ventilation and extubation more difficult.

The electrocardiogram should be monitored continuously during the postoperative period. A change in heart rate, even without arrhythmia, may be the first indication of a serious complication such as hemorrhage, hypothermia, hypoventilation, or heart failure. **Cardiac rhythm disorders** must be diagnosed quickly because a prolonged untreated arrhythmia may add a severe hemodynamic burden to the heart in the critical early postoperative period (see Chapter 435). Injury to the heart's conduction system during surgery can result in postoperative complete heart block. This complication is usually temporary and is treated with surgically placed pacing wires that can later be removed. Occasionally, complete heart block is permanent. If heart block persists beyond 10-14 days postoperatively, insertion of a permanent pacemaker is required. Tachyarrhythmias are a common problem in postoperative patients. Junctional ectopic tachycardia can be a particularly troublesome rhythm to manage (see Chapter 435), although it usually responds to antiarrhythmic medications such as intravenous amiodarone.

Heart failure with poor cardiac output after cardiac surgery may be secondary to respiratory failure, serious arrhythmias, myocardial injury, blood loss, hypovolemia, a significant residual hemodynamic abnormality, or any combination of these factors. Treatment specific to the cause should be instituted. Catecholamines, phosphodiesterase inhibitors, nitroprusside and other afterload-reducing agents, and diuretics are the cardioactive agents most often used in patients with myocardial dysfunction in the early postoperative period (see Chapter 442). Postoperative pulmonary hypertension can be managed with hyperventilation and inhaled nitric oxide. In the rare patients who are unresponsive to standard pharmacologic treatment, various ventricular assist devices are available, depending on the patient's size. If pulmonary function is adequate, a left ventricular assist device may be used. If pulmonary function is inadequate, extracorporeal membrane oxygenation may be used. These extraordinary measures are helpful in maintaining the circulation until cardiac function improves, usually

within 2-5 days. They have also been used as a bridge to transplantation in patients with severe nonremitting postoperative cardiac failure.

Acidosis secondary to low cardiac output, renal failure, or hypovolemia must be prevented, or if present, promptly corrected. Serial monitoring of arterial blood gases and lactate concentrations is performed. A low arterial pH may not only be a sign of decreased perfusion, but also worsen cardiac function and may be the forerunner of arrhythmias or cardiac arrest.

Renal function may be compromised by congestive heart failure and further impaired by prolonged cardiopulmonary bypass. Blood and fluid replacement, cardiac inotropic agents, and vasodilators will usually reestablish normal urine flow in patients with hypovolemia or cardiac failure. Renal failure secondary to tubular injury may require temporary peritoneal or hemodialysis or hemofiltration.

Neurologic abnormalities can develop after cardiopulmonary bypass, especially in the neonatal period. Seizures may occur when the patient awakens from sedation and can usually be controlled with anticonvulsant medications. In the absence of other neurologic signs, self-limited isolated seizures in the immediate postoperative period usually carry a good long-term prognosis. Thromboembolism and stroke are rarer but serious complications of open heart surgery. In the long-term, both subtle and more substantial learning disabilities may develop. Patients who have undergone surgery entailing the use of cardiopulmonary bypass, especially in the newborn period, should be watched carefully during their early school years for signs of mild to moderate learning disabilities or attention deficit disorders, which are often amenable to early remedial intervention. The risk is higher in patients who have undergone repair using hypothermic total circulatory arrest than in those where systemic blood flow is maintained using cardiopulmonary bypass.

The **postpericardiotomy syndrome** may occur toward the end of the 1st postoperative wk or may sometimes be delayed until weeks or months after surgery. This febrile illness is characterized by fever, decreased appetite, listlessness, nausea, and vomiting. Chest pain is not always present, so a high index of suspicion should be maintained in any recently postoperative patient. Echocardiography is diagnostic. In most instances, the postpericardiotomy syndrome is self-limited; however, when pericardial fluid accumulates rapidly, the potential danger of cardiac tamponade should be recognized (see Chapter 440). Rarely, arrhythmias may also occur. Symptomatic patients usually respond to salicylates or indomethacin and bed rest. Occasionally, steroid therapy or pericardiocentesis is required. Late recurrences are rare and can lead to chronic pericarditis.

Hemolysis of mechanical origin is seen, although rarely, after repair of certain cardiac defects, for example, atrioventricular septal defects (AVSDs), or after the insertion of a mechanical prosthetic valve. It is caused by unusual turbulence of blood at increased pressure. Reoperation may be necessary in rare patients with severe and progressive hemolysis who require frequent blood transfusions, but in most instances, the problem slowly regresses.

Infection is another potentially serious postoperative problem. Patients usually receive a broad-spectrum antibiotic for the initial postoperative period. Potential sites of infection include the lungs (generally related to postoperative atelectasis), the subcutaneous tissues at the incision site, the sternum, and the urinary tract (especially after an indwelling catheter has been in place). Sepsis with infective endocarditis is an infrequent complication, and can be difficult to manage, especially if prosthetic material was placed at the time of surgery (see Chapter 437).

LONG-TERM MANAGEMENT

Patients who have undergone surgery for congenital heart disease can be divided into several major categories: (1) lesions for which total repair has been achieved; (2) lesions for which both anatomic and physiologic correction have been achieved; and (3) lesions for which only palliation, albeit potentially long-term, has been achieved. There is some disagreement among cardiologists as to exactly which categories a particular congenital heart lesion might fall, and to some degree every case should be considered individually. Many argue that only for isolated patent ductus arteriosus is total repair really achieved, with no requirement for long-term follow-up. Patients who are able to undergo anatomic and physiologic correction include many of the left-to-right shunt lesions (atrial and ventricular septal defects) and milder forms of obstructive lesions (e.g., valvar pulmonic stenosis, some forms of valvar aortic stenosis, and coarctation of the aorta), and some forms of cyanotic heart disease, for example, uncomplicated tetralogy of Fallot and simple transposition of the great arteries. These patients usually have achieved total or near-total physiologic correction of their lesion; however, they are still at some risk of long-term sequelae, including late heart failure or arrhythmia, or recurrence of a significant physiologic abnormality (e.g., recoarctation of the aorta, worsening mitral regurgitation in patients with AVSDs, or long-standing pulmonary regurgitation in patients with tetralogy of Fallot repaired with a transannular patch). These patients require regular follow-up with a pediatric cardiologist (and when old enough, with an **adult congenital heart disease specialist** [see Chapter 434.1]); however, their long-term prognosis is generally very good, although some will require repeat surgeries. Patients with more complex lesions, such as those with single-ventricle physiology, are at much higher risk of long-term sequelae and require even closer follow-up. These patients, particularly those who have undergone the Fontan procedure, are at risk long-term for arrhythmia, thrombosis, protein losing enteropathy, end-organ (especially hepatic) dysfunction, and heart failure. Some may eventually require cardiac transplantation.

Physical limitations are variable, ranging from minimal to none in patients with physiologic correction, to mild to moderate in patients with palliative procedures. The extent to which a patient should be allowed to participate in athletics, both recreational and competitive, can best be determined by the cardiologist, often with the assistance of the data that can be derived from cardiopulmonary exercise testing (see Chapter 423.5).

Long-term morbidities affecting neurologic function and behavior are influenced by many factors, including the effects of any genetic alterations on the developing central nervous system. Data suggest a greater role for prenatal central nervous system abnormalities (anatomic or secondary to alterations in cerebral blood flow or oxygenation) than previously suspected; these include microcephaly, cerebral atrophy, and altered cerebral biochemistry. Chronic hypoxemia and failure to thrive also may influence the developing brain, and there is evidence that the type of intervention required (cardiopulmonary bypass, hypothermic total circulatory arrest, catheter-based therapy) plays a substantial role. In general, in the absence of a significant genetic syndrome or major perioperative complication, most children function at a fairly high level after repair of congenital heart defects and are able to attend regular school. Group mean scores on standard cognitive tests are not different from the general population; however, some areas appear to be more at risk than others, including certain aspects of motor function, speech, visual-motor tracking, and phonologic awareness. Awareness of these potential issues is critical to obtaining prompt remedial assistance if a child is found to be struggling in school.

Bibliography is available at Expert Consult.

434.1 Congenital Heart Disease in Adults

Salil Ginde and Michael G. Earing

The advent of cardiac surgical procedures such as ligation of patent ductus arteriosus, resection of coarctation of aorta, and the Blalock-Taussig shunt, as well as advances in diagnostic, interventional, and critical care skills have resulted in survival of approximately 90% of children with congenital heart disease to adulthood. More adults than children are living with congenital heart disease in the United States, with a 5% increase every year. In the last decade, 35% of hospitalizations for congenital heart disease were patients over the age of 18 yr (mean age: 55 yr).

LONG-TERM MEDICAL CONSIDERATIONS

Approximately 25% of adults with congenital heart disease have a mild form that has allowed them to survive into adulthood without surgical

or interventional cardiac catheterization. The most common lesions in this category include mild aortic valve stenosis (usually in setting of bicuspid aortic valve), small restrictive ventricular septal defects, mild pulmonary valve stenosis, and mitral valve prolapse (Table 434-2). These patients need less-frequent follow-up to assess for progression of disease and to identify associated complications. The majority of adults with congenital heart disease living in the United States are patients who have had previous intervention (Table 434-3). Although most children who undergo surgical intervention will survive to adulthood, with few exceptions, total correction is not the rule. The few exceptions include patent ductus arteriosus, ventricular septal defects, and atrial septal defects; this is true only if they are closed early before the development of irreversible pulmonary vascular changes, and no residual lesions exist.

Because adult patients with congenital heart disease (CHD) are surviving longer than ever, it is becoming increasingly apparent that even the simplest lesions can be associated with long-term complications. These long-term complications include both cardiac and noncardiac problems (Tables 434-4 and 434-5, Fig. 434-1). Cardiac complications include arrhythmias and conduction defects, ventricular dysfunction, residual shunts, valvular lesions (regurgitation and stenosis), hypertension, and aneurysms. Noncardiac sequelae (comorbidities) include pulmonary, renal, and hepatic dysfunction that is caused either directly or indirectly by the underlying CHD. Abnormal pulmonary function most commonly presents as restrictive lung physiology, and likely results from prior sternotomy or thoracotomy, scoliosis, diaphragmatic dysfunction, or parenchymal lung disease. Reduced pulmonary function contributes to reduced exercise tolerance and is a risk factor for mortality in adults with CHD. Renal dysfunction may result from chronic cyanosis, multiple surgeries requiring cardiopulmonary bypass, or from other comorbid conditions, such as hypertension and diabetes mellitus. Hepatic injury from chronic liver congestion in patients with elevated central venous pressures, particularly patients palliated with the Fontan procedure, can result in hepatic fibrosis, cirrhosis, hepatic dysfunction and rarely hepatocellular carcinoma. Adults with CHD are at risk for developmental abnormalities such as intellectual impairment, somatic abnormalities such as facial dysmorphism (cleft palate/lip), central nervous abnormalities such as seizure disorders from previous thromboembolic events or cerebrovascular accidents, and impairments of hearing or vision loss. Psychosocial problems involving employment, life and health insurance, participation in sports, sexual activity, and contraception are common. As a result of these long-term complications, the majority of adults with CHD need lifelong follow-up. When adults with CHD are hospitalized, it is usually for heart failure or an arrhythmia; others may require catheterization or another cardiac surgical procedure.

Table 434-2	Congenital Heart Defects Associated with Survival into Adulthood Without Surgery or Interventional Cardiac Catheterization
Mild pulmonary valve stenosis	
Bicuspid aortic valve	
Small to moderate size atrial septal defect	
Small ventricular septal defect	
Small patent ductus arteriosus	
Mitral valve prolapse	
Partial atrioventricular canal (ostium primum atrial septal defect and cleft mitral valve)	
Marfan syndrome	
Ebstein anomaly	
Congenitally corrected transposition (atrioventricular and ventriculoarterial discordance)	

Table 434-3	Most Common Congenital Heart Defects Surviving to Adulthood After Surgery or Interventional Catheterization
Aortic valve disease following balloon valvuloplasty or surgical valvotomy	
Pulmonary valve stenosis following balloon valvuloplasty or surgical valvotomy	
Tetralogy of Fallot	
Ventricular septal defect	
Complete atrioventricular canal defect	
Transposition of the great arteries	
Coarctation of the aorta	
Complex single ventricles after the modified Fontan procedure	

SPECIFIC LESIONS

Left-to-Right Shunts

If the initial lesion has a shunt that is large and nonrestrictive (allowing transmission of near systemic pressure to the pulmonary arteries), irreversible pulmonary vascular changes can occur, resulting in pulmonary hypertension at systemic levels with reversed or bidirectional shunting at the level of the defect (Eisenmenger syndrome) (see Chapter 433.2).

Atrial Septal Defects

See Chapter 426.1.

Although, most individuals with an atrial septal defect are diagnosed during childhood after a murmur is noted, a minority of patients

Table 434-4	Risks in Adults Who Have Congenital Heart Disease
Rhythm disorder	Ventral septal defect
Supraventricular tachycardia	Atrial septal defect
Right bundle branch block	Patent ductus arteriosus
Heart block	**Acquired lesions**
Ventricular tachycardia	Subacute bacterial endocarditis
Sudden death	Subvalvular stenosis
Coarctation of aorta	Supravalvular stenosis
Essential hypertension	Valvular insufficiency
Recoarctation	Valvular restenosis
Aneurysm formation	Eisenmenger complex
Residual lesions (shunts)	**Pregnancy risk (see Table 434-5)**

Table 434-5	Lesion Specific Risks of Maternal and Neonatal Complications of Pregnancy
No additional risk	Small septal defects Surgically closed ASD, VSD, PDA Mild to moderate aortic regurgitation Mild to moderate pulmonary stenosis
Slightly increased risk	Postoperative repair of tetralogy of Fallot Transposition of the great arteries, s/p arterial switch procedure
Moderate risk	Transposition of the great arteries, s/p atrial switch procedure Congenitally corrected transposition of the great arteries Single ventricle physiology, s/p Fontan procedure
Severe risk	Cyanotic congenital heart disease, unoperated or palliated Marfan syndrome Prosthetic valves Obstructive lesions including coarctation
Pregnancy contraindicated	Severe pulmonary hypertension Severe obstructive lesions Marfan syndrome, aortic root >40 mm

ASD, atrial septal defect; PDA, patent ductus arteriosus; s/p, status post (after); VSD, ventricular septal defect.

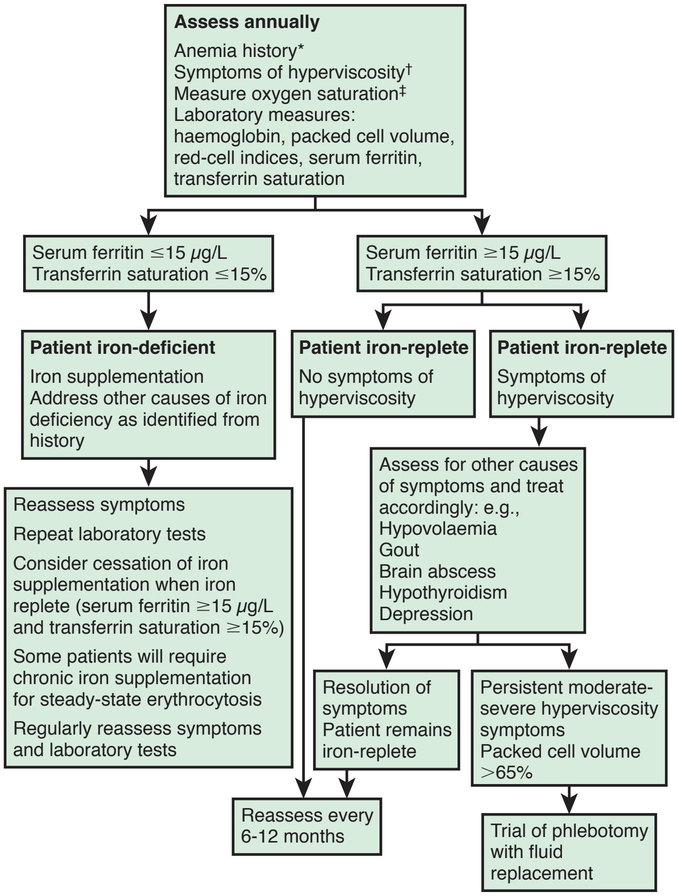

Figure 434-1 Important issues that are crucial to address at time of transition. *(From Spence MS, Balaratnam MS, Gatzoulis MA: Clinical update: cyanotic adult congenital heart disease,* Lancet *370:1530–1532, 2007, p. 1531.)*

present with symptoms for the 1st time as adults. Most patients are asymptomatic during the 1st and 2nd decades of life. In the 3rd decade, an increasing number of patients then develop exercise intolerance, palpitations from atrial arrhythmias, and cardiac enlargement. If untreated, survival into adulthood is the rule; life expectancy, however, is not normal and there is significant long-term morbidity. After the age of 40 yr, the mortality rate increases by 6% per year, and more than 20% of patients will have developed atrial fibrillation. By age 60 yr, the number of patients with atrial fibrillation increases to more than 60%.

Late Outcome Following Closure of Atrial Septal Defect

Most patients who have undergone early closure of a defect will have excellent long-term survival with low morbidity if repair is undertaken before age 25 yr. Older age of repair is associated with decreased late survival with an associated increased risk for the development of atrial arrhythmias, thromboembolic event, and pulmonary hypertension. Long-term late complications and survival following transcatheter device closure remain unknown; early and intermediate results are excellent with a high rate of atrial septal defect closure and few major complications.

Ventricular Septal Defects

See Chapter 426.6.

Although isolated ventricular septal defects (VSDs) are 1 of the most common forms of CHD, the diagnosis of a VSD in an adult is rare. The primary reason for this is that most patients with a hemodynamically significant VSD will have undergone repair in childhood or will have died earlier in life. As result, the spectrum of isolated VSD in adults is limited to (1) those with small restrictive defects, (2) those with Eisenmenger syndrome, and (3) those who had their defects closed in childhood.

For patients with small restrictive VSD, the long-term survival is excellent with estimated 25-yr survival of 96%. In addition, the long-term morbidity for patients with a restrictive VSD also appears to be low. Their clinical course is not completely benign. Reported long-term complications include endocarditis, progressive aortic regurgitation secondary to prolapse of aortic valve into the defect (highest risk is with supracristal type, but also can occur in setting of perimembranous defect), and the development of both right and left outflow tract obstruction from a double-chamber right ventricle or a subaortic membrane. For those patients who develop Eisenmenger syndrome, survival into the 3rd decade is common. With increasing age, the long-term complications of right-heart failure, paradoxical emboli, and polycythemia, usually result in progressive decline in survival, with an average age of death of 37 yr.

Adults with previous VSD closure, without pulmonary hypertension or residual defects, live a normal life expectancy. Because patients with small VSDs are asymptomatic, these patients should be managed conservatively. Given the long-term risks, they do need intermittent follow-up for life to monitor for the development of late complications. The exception to this rule is patients with small supracristal or perimembranous VSD with associated prolapse of the aortic cusp into the defect resulting in progressive aortic regurgitation. These patients should be considered for surgical repair at the time of diagnosis to prevent progressive aortic valve damage.

Complete Atrioventricular Canal

See Chapter 426.5.

The natural history for patients with complete AVSD is characterized by the early development of pulmonary vascular disease, leading to irreversible damage often by age 1 yr (especially in children with Down syndrome). Thus, patients who present in adulthood can be categorized into 2 groups: (1) those with Eisenmenger syndrome and (2) those who had their defects closed in childhood.

Overall, for those patients who underwent early repair before the development of pulmonary vascular disease, the long-term prognosis is good. The most common long-term complication is left atrioventricular valve regurgitation, with approximately 5-10% of patients requiring surgical revision for left atrioventricular valve repair or replacement during follow-up. The second most common long-term complication for this patient group is subaortic stenosis, occurring in up to 5% of patients after repair. Other long-term complications include residual atrial or ventricular level shunts, complete heart block, atrial and ventricular arrhythmias, and endocarditis.

For those patients who have developed Eisenmenger syndrome, all are symptomatic with exertional dyspnea, fatigue, palpitations, edema, and syncope. Survival is similar to other forms of Eisenmenger syndrome, with a mean age of death of 37 yr. Strong predictors for death include syncope, age at presentation of symptoms, poor functional class, low oxygen saturation (<85%), elevated serum creatinine and serum uric acid concentrations, and Down syndrome.

Patients who underwent previous repair and develop significant left atrioventricular valve regurgitation causing symptoms, atrial arrhythmias, or deterioration in ventricular function should undergo elective valve repair or replacement. Those previously repaired patients who develop significant subaortic stenosis (defined as a peak cardiac catheterization or echo gradient of >50 mm Hg) should undergo surgical repair.

Patent Ductus Arteriosus

See Chapter 426.8.

A patent ductus arteriosus (PDA) is usually an isolated lesion in the adult patient. The size of the defect is the primary determinant of clinical course in the adult patient. These clinical courses can be grouped

into 5 main categories: (1) silent PDAs; (2) small, hemodynamically insignificant PDAs; (3) moderate size PDAs; (4) large PDAs; and (5) previously repaired PDAs.

A silent PDA is a tiny defect that cannot be heard by auscultation and is only detected by other nonclinical means such as echocardiography. Life expectancy is always normal in this population and the risk for endocarditis is extremely low.

Patients with a small PDA have an audible long-ejection or continuous murmur heard best at the left upper sternal border that radiates to the back. In addition, they have normal peripheral pulses. Because there is negligible left to right shunting these patients have normal left aorta and left ventricle (LV) size and normal pulmonary artery pressure by echocardiography and chest x-ray. These patients like those with silent PDAs are asymptomatic and live a normal life expectancy. They have a higher risk for endocarditis.

Patients with moderate size PDAs may present during adulthood. These patients often will have wide, bounding peripheral pulses and an audible continuous murmur. These patients all have significant volume overload and develop some degree of left aorta and LV enlargement and some degree of pulmonary hypertension. These patients are symptomatic with dyspnea, palpitations, and heart failure.

Patients with large PDAs typically present with signs of severe pulmonary hypertension and Eisenmenger syndrome. By adulthood, the continuous murmur is typically absent and there is differential cyanosis (lower extremity saturations lower than the right arm saturation). These patients have a similar prognosis as other patients with Eisenmenger syndrome.

Patients who underwent repair of a PDA prior to the development of pulmonary hypertension have a normal life expectancy without restrictions.

All patients with *clinical evidence* of a PDA are at increased risk for endocarditis. As result, all PDAs except for small silent PDAs and those patients with severe irreversible pulmonary hypertension should be considered for closure. Catheter device closure is the preferred method in most centers today. Surgical closure is reserved for patients with PDAs too large for device closure or when the anatomy is distorted, such as in the setting of a large ductal aneurysm.

Cyanotic Heart Disease

See Chapters 429, 430, and 431.

Unlike the acyanotic forms of CHD, the majority of patients with cyanotic CHD will have had at least 1 and often several previous interventions prior to adulthood. The most frequent defects seen in the outpatient adult congenital setting is tetralogy of Fallot, complete transposition of the great arteries (TGA, also known as d-transposition), pulmonary valve stenosis, and various forms of single ventricles. Other defects include total anomalous pulmonary venous return, truncus arteriosus, and double-outlet right ventricle.

Tetralogy of Fallot

See Chapter 430.1.

In the developed world, the unoperated adult patient with tetralogy of Fallot has become a rarity because the majority of patients will have undergone palliation or, more often, repair in childhood. Survival in the unoperated patient to the 7th decade has been described but is rare. In general, only 11% of unoperated patients are alive by age 20 yr and only 3% by age 40 yr.

Late survival following repair of tetralogy of Fallot is excellent. Repair is typically performed at 3-12 mo of age and consists of patch closure of the VSD and relief of the pulmonary outflow tract obstruction by patch augmentation of the right ventricular outflow tract, pulmonary valve annulus, or both. Survival rates at 32 and 35 yr have been reported to be 86% and 85%, respectively, compared to 95% in age- and sex-matched controls. Most patients lived an unrestricted life. Many patients do develop late symptoms that include exertional dyspnea, palpitations, syncope, and sudden cardiac death. Late complications include endocarditis, aortic regurgitation with or without aortic root dilation (typically caused by damage of the aortic valve during VSD closure or secondary to an intrinsic aortic root abnormality), LV dysfunction (secondary to inadequate myocardial protection during previous repair or chronic left ventricular volume overload caused by long-standing palliative arterial shunts), residual pulmonary valve obstruction, residual pulmonary valve regurgitation, right ventricular (RV) dysfunction (as a result of pulmonary regurgitation or pulmonary stenosis), atrial arrhythmias (typically atrial flutter), ventricular arrhythmias, and heart block.

Reintervention is necessary in approximately 10% of patients following reparative surgery at 20-year follow-up. With longer follow-up, the incidence of reintervention continues to increase. The most common indication for reintervention is pulmonary valve replacement for severe pulmonary valve regurgitation.

Transposition of the Great Arteries

See Chapter 431.1.

The natural history of patients with unrepaired TGA is so poor that very few patients survive past childhood without intervention. The first definitive operations for TGA were described by Dr. Senning in 1959 and Dr. Mustard in 1964 (atrial switch procedures). With these procedures, the systemic and pulmonary venous returns are rerouted in the atrium by constructing baffles. The systemic venous return from the superior and inferior vena cavae is directed through the mitral valve and into the LV (connected to the pulmonary artery). The pulmonary venous return is then directed through the tricuspid valve into the right ventricular (connected to the aorta). These procedures can be performed with low mortality but leave the LV as the pulmonary ventricle and the right ventricle as the systemic ventricle. Long-term follow-up studies after the atrial switch procedure show a small but ongoing attrition rate with numerous other intermediate and long-term complications. Two specific problems after the atrial switch procedure are most concerning. These include the loss of sinus rhythm with the development of atrial arrhythmias, occurring at an incidence of 50% by age 25 yr, and the development of systemic ventricular dysfunction, occurring at an incidence of 50% by age 35 yr. Other long-term complications include endocarditis, baffle leaks, baffle obstruction, tricuspid valve regurgitation, and sinus node dysfunction requiring pacemaker placement.

As result of these long-term complications, the arterial switch operation has become the procedure of choice to treat these patients since 1985. During the arterial switch procedure, the great arteries are transected and reanastomosed to the correct ventricle (LV to the aorta and the right ventricle to the pulmonary artery) with coronary artery transfer. Operative survival after the arterial switch procedure in the current surgical era is very good, with a surgical mortality rate of 2-5%. Long-term data on survival and complications does not exist, but intermediate results are promising. Reported intermediate complications include endocarditis, pulmonary outflow tract obstruction (at the supravalvular level or at the takeoff of the peripheral pulmonary arteries), aortic valve regurgitation, and coronary artery compromise (ranging from minor stenosis to complete occlusion).

Because of the high incidence of observed and potential medical problems, all patients who have had both atrial and arterial repair of TGA should have lifelong follow-up by a cardiologist at a center specializing in adult CHD.

Pulmonary Valve Stenosis

See Chapter 427.1.

Most patients with pulmonary valve stenosis are asymptomatic and present with a cardiac murmur. Survival into adult life and the need for intervention however is directly correlated to the degree of obstruction. Patients with trivial stenosis (defined as a peak gradient <25 mm Hg) followed for 25 yr remain asymptomatic and have no significant progression of obstruction over time. For those patients with moderate pulmonary valve stenosis (defined as a peak gradient of 25-49 mm Hg), there is an approximately 20% chance of requiring intervention by age 25 yr. For those patients with severe stenosis (defined as a peak gradient of >50 mm Hg), the majority ultimately require an intervention, either surgery or balloon valvuloplasty by age 25 yr.

Following surgical valvotomy for isolated pulmonary stenosis, long-term survival is excellent. With longer follow-up the incidence of late complications and the need for reintervention do increase. The most common indication for reintervention is pulmonary valve replacement for severe pulmonary regurgitation. Other long-term complications include recurrent atrial arrhythmias, endocarditis, and residual RV outflow tract obstruction.

Patients with moderate to severe pulmonary stenosis (defined as a peak gradient of >50 mm Hg) should be considered for intervention even in the absence of symptoms. Since 1985, percutaneous balloon valvuloplasty has been the accepted treatment for patients of all ages. Prior to 1985, surgical valvotomy had been the gold standard. Surgical valvotomy is reserved for those patients who are unlikely to have successful results from balloon valvuloplasty, such as those with an extremely dysplastic or calcified valve.

Left-Sided Obstructive Lesions

Coarctation of the Aorta

See Chapter 427.6.

The clinical presentation of coarctation of the aorta depends on the severity of obstruction and the associated anomalies. Unrepaired coarctation of the aorta typically presents with symptoms prior to adulthood. These symptoms include headaches related to hypertension, leg fatigue or cramps, exercise intolerance, and systemic hypertension. Those untreated patients surviving to adulthood thus typically have only mild coarctation of the aorta. In the era prior to surgery, without treatment the mean age of death was 32 yr. Causes of death included left ventricular failure, intracranial hemorrhage, endocarditis, aortic rupture/dissection, and premature coronary artery disease.

Following surgical repair, long-term survival is good but is directly correlated with the age at repair, with those repaired after age 14 yr having a lower 20 yr survival than those who were repaired earlier, 91% compared to 79%. With longer follow-up the incidence of long-term complications continues to rise. The most common long-term complication is persistent or new systemic hypertension at rest or during exercise. Other long-term complications include aneurysms of the ascending or descending aorta, recoarctation at the site of previous repair, coronary artery disease, aortic stenosis or regurgitation (in setting of bicuspid aortic valve), rupture of an intracranial aneurysm, and endocarditis.

Patients with significant native or residual coarctation of the aorta (symptomatic patients with a peak gradient across the coarctation of >20 mm Hg) should be considered for intervention, either surgery or catheter intervention with balloon angioplasty with or without stent placement. Surgical repair in the adult patient is technically difficult and is associated with high morbidity. Catheter based intervention has become the preferred method in most experienced adult CHD centers.

Aortic Valve Stenosis

See Chapter 427.5.

The natural history of aortic valve stenosis in adults is quite variable but is characterized by progressive stenosis over time. By age 45 yr, approximately 50% of bicuspid aortic valves will have some degree of stenosis.

Most patients with aortic valve stenosis are asymptomatic and are diagnosed after a murmur is detected. The severity of obstruction at the time of diagnosis correlates with the pattern of progression. Symptoms are rare until patients have severe aortic valve stenosis (mean gradient by echocardiography of >40 mm Hg). Symptoms include chest pain, exertional dyspnea, near syncope, and syncope. When any of these symptoms are present, the risk of sudden cardiac death is very high and as result, surgical intervention is mandated. For patients requiring surgical valvotomy to relieve the stenosis prior to adulthood, the majority of patients do well. However, at 25 yr follow-up, up to 40% of patients will have required a second operation for residual stenosis or regurgitation.

Patients with symptoms and severe aortic valve stenosis should be considered for intervention. Treatment involves manipulating the valve to reduce stenosis. This can be accomplished by transvenous balloon dilation of the valve, open surgical valvotomy, or valve replacement. In absence of significant aortic regurgitation, most centers favor balloon dilation or surgical valvotomy for children and young adults who have pliable valves with fusion of commissures. In older adults, aortic valve replacement is the treatment of choice.

Endocarditis Prophylaxis

See Chapter 437.

The American Heart Association found that very few cases of endocarditis are prevented with antibiotic prophylaxis. Only patients with cardiac conditions associated with the highest risk for adverse outcomes should continue follow antibiotic prophylaxis before surgery: patients with previous endocarditis, unrepaired cyanotic CHD, including palliative shunts and conduits; completely repaired congenital heart defects with prosthetic material or device, whether placed by surgery or by catheter intervention, during the 1st 6 mo after the procedure; and repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization). Except for the conditions just listed, antibiotic prophylaxis is no longer recommended for other forms of CHD.

PREGNANCY AND CONGENITAL HEART DISEASE

CHD is the most common form of heart disease encountered during pregnancy in developed countries. Heart disease does not preclude a successful pregnancy but increases the risk to both the mother and the baby. During pregnancy there are substantial hemodynamic changes that occur. The hemodynamic changes in pregnancy result in a steady increase in cardiac output during pregnancy until the 32nd wk of gestation, at which time, the cardiac output reaches a plateau at 30-50% above the prepregnancy level. At time of delivery, with uterine contractions an additional 300-500 mL of blood enters the circulation. This in conjunction with increased blood pressure and heart rate during labor increases the cardiac output at delivery to 80% the prepregnancy level.

Despite these hemodynamic changes, the outcome of pregnancy is favorable in most women with CHD provided that functional class and systemic ventricular function are good (see Table 434-5). Pulmonary artery hypertension presents a serious risk during pregnancy, particularly when the pulmonary pressure exceeds 70% of systemic pressure, regardless of functional class. Other contraindications to pregnancy include severe obstructive left-sided lesions (coarctation of the aorta, aortic valve stenosis, mitral valve stenosis, hypertrophic cardiomyopathy), Marfan syndrome with coexisting dilated ascending aorta (defined as >4 cm), persistent cyanosis, and systemic ventricular dysfunction (ejection fraction of ≤40%). The need for full anticoagulation during pregnancy, although not a contraindication, poses an increased risk to both mother and fetus. The relative risks and benefits of the different anticoagulant approaches need to be discussed fully with the prospective mother.

Pregnancy counseling should begin early in adolescence and should be part of the routine cardiac follow-up visit. During counseling, a discussion about the risk of CHD in the offspring should take place. In the general population, the incidence of CHD is 1%. In the offspring of a mother with CHD, the risk increases to 5-6%. Often the cardiac lesion in the offspring is not the same as that in the mother, except for in the case of a syndrome with autosomal dominant inheritance (Marfan syndrome, hypertrophic cardiomyopathy). Risk stratification should include the specific CHD lesion but also needs to take in account the maternal functional class. Although the specific CHD lesion is important, multiple studies demonstrate that the maternal functional class prior to pregnancy is highly predictive of both maternal and fetal outcomes, with those having the best functional class having the best outcomes.

CONTRACEPTION

A critical part of caring for adults with CHD is to provide or make available advice on contraception. Unfortunately, there are limited data on the safety of various contraceptive techniques in adult CHD patients. The estrogen-containing oral contraceptive pill can be used in many adult CHD patients but is not recommended in adult CHD patients at risk of thromboembolism, such as those with cyanosis, prior

Table 434-6	Issues That Require Coordination of Care Between the Cardiologist and the Primary Care Physician

Fontan procedure, atrial fibrillation, or pulmonary artery hypertension. In addition, this form of contraceptive therapy may upset anticoagulation control. Although slightly less effective than contraceptive pills containing combined estrogen/progesterone, medroxyprogesterone, the progesterone-only pills, and levonorgestrel are good options for most adult CHD patients. Medroxyprogesterone and levonorgestrel, however, can cause fluid retention and thus need to be used with caution in patients with heart failure. These medications are also associated with depression and often breakthrough bleeding. Tubal ligation, although the most secure method of contraception, can be a high-risk procedure in patients with complex CHD or those with pulmonary hypertension. Hysteroscopic sterilization (Essure) may be reasonable for high-risk patients. In the past, intrauterine devices were seldom used in cardiac patients because of the associated risk of bacteremia, pelvic inflammatory disease, and endocarditis. Intrauterine devices such as the Mirena, appear to be safe and effective, and are rapidly becoming one of the most commonly used form of contraception in the adult CHD population.

ADOLESCENT TRANSITION

It is well recognized that, as part of the process of obtaining independence, adolescents or young adults must develop a forward-looking, independent approach to their medical care. For children with heart disease, the transition process must begin during early adolescence and should be encouraged by both the primary care provider and the pediatric cardiologist, who must identify an appropriate adult congenital heart program to which transition and transfer will be made at an appropriate time (Table 434-6).

A successful transition program includes the following elements:

- Development of a written transition plan that should begin by the age of 14 yr
- Because adolescents and young adults are frequently unaware of the details of their cardiac diagnosis and history, a complete, concise, portable medical record, including all pertinent aspects of cardiac care, should be shared with adolescents and their families and prepared for transmittal to the eventual adult care destination.
- The primary care provider and cardiologist must address unique adolescent medical issues as they impact the cardiovascular system. In addition to medical problems, education, vocational planning, psychosocial issues, and access to medical care are all topics that should be discussed with adolescents and their families.

There is a tendency for young adults to avoid medical care because of lack of education, denial, or difficulty with access to the medical care system. Thus, a critical goal of the adolescent transition process is to identify an appropriate site for ongoing medical care and ensure maintenance of the medical record and continuity of care for the young adult. The site of care for a young adult with CHD may be a pediatric program or facility, or may be a specialized center or program for the adult with CHD. The critical issues are the continuity of care, the preparation of the patient, and the patient's participation in the process.

Section 4

Cardiac Arrhythmias

Chapter 435

Disturbances of Rate and Rhythm of the Heart

George F. Van Hare

The term *arrhythmia* refers to a disturbance in heart rate or rhythm. Such disturbances can lead to heart rates that are abnormally fast, slow, or irregular. They may be transient or incessant, congenital or acquired, or caused by a toxin or by drugs. They may be associated with particular forms of congenital heart disease, may be a complication of surgical repair of congenital heart disease, may be a result of certain genetic causes, or may be a result of fetal inflammation such as in maternal connective tissue disease. Arrhythmias, either slow or fast, may lead to acutely decreased cardiac output, degeneration into a more dangerous arrhythmia such as ventricular fibrillation, or if incessant may lead to cardiomyopathy. Arrhythmias may lead to syncope or to sudden death. When a patient has an arrhythmia, it is important to determine whether the particular rhythm is likely to lead to severe symptoms or to deteriorate into a life-threatening condition. Rhythm abnormalities, such as single premature atrial and ventricular beats, are common and in children without heart disease, in most instances do not pose a risk to the patient.

A number of pharmacologic agents are available for treating arrhythmias; many have not been studied extensively in children. Insufficient data are available regarding pharmacokinetics, pharmacodynamics, and efficacy in the pediatric population, and therefore the selection of an appropriate agent is necessarily empirical. Fortunately, the majority of rhythm disturbances in children can be reliably controlled with a single agent (Table 435-1). Increasingly, transcatheter ablation is acceptable therapy not only for life-threatening or drug-resistant arrhythmias, but also for the cure of arrhythmias. For patients with bradycardia, implantable pacemakers are small enough for use in all ages, and even in premature infants. Implantable cardioverter-defibrillators (ICDs) are available for use in high-risk patients with malignant ventricular arrhythmias and an increased risk of sudden death.

435.1 Principles of Antiarrhythmic Therapy

George F. Van Hare

When considering drug therapy in the pediatric population, it is important to recognize that there may be marked differences in pharmacokinetics by age and in comparison with adults. Infants may have slower absorption, slow gastric emptying, and differing sizes of drug tissue compartments affecting the volume of distribution. Hepatic metabolism and renal excretion may vary within the pediatric age group as well as in comparison to adults. When considering antiarrhythmic therapy, it is important to recognize that the likely arrhythmia mechanism may be different for the pediatric vs. adult population.

There are many antiarrhythmic agents available for rhythm control. The majority have not been approved by the FDA for use in children; their use is therefore considered "off-label." Pediatric cardiologists have experience with these drugs, and there are well-recognized standards regarding dosing.

With the availability of potentially curative ablation procedures, medical therapy has become less important. Clinicians and patients accept fewer drug side effects. Intolerable side effects, as well as the potential for a proarrhythmia induced by an antiarrhythmic drug, can seriously limit medical therapy and will lead the physician and family toward a potentially curative ablation procedure.

Antiarrhythmic drugs are commonly categorized using the Vaughan Williams classification system. This system comprises 4 classes: Class I includes agents that primarily block the sodium channel, class II includes the β-blockers, class III includes those agents that prolong repolarization, and class IV are the calcium channel blockers. Class I is further divided by the strength of the sodium channel blockade (see Table 435-1).

Table 435-1 Antiarrhythmic Drugs Commonly Used in Pediatric Patients, by Class

DRUG	INDICATIONS	DOSING	SIDE EFFECTS	DRUG INTERACTIONS	DRUG LEVEL
CLASS IA: INHIBITS NA$^+$ FAST CHANNEL, PROLONGS REPOLARIZATION					
Quinidine	SVT, atrial fibrillation, atrial flutter, VT. In atrial flutter, an AV node blocking drug (digoxin, verapamil, propranolol) must be given first to prevent 1:1 conduction	Oral: 30-60 mg/kg/24 hr divided q6h (sulfate) or q8h (gluconate) In adults, 10 mg/kg/day divided q6h Max dose: 2.4g/24 hr	Nausea, vomiting, diarrhea, fever, cinchonism, QRS and QT prolongation, AV nodal block, asystole syncope, thrombocytopenia, hemolytic anemia, SLE, blurred vision, convulsions, allergic reactions, exacerbation of periodic paralysis	Enhances digoxin, may increase PTT when given with warfarin	2-6 µg/mL
Procainamide	SVT, atrial fibrillation, atrial flutter, VT	Oral: 15-50 mg/kg/24 hr divided q4h Max dose: 4 g/24 hr IV: 10-15 mg/kg over 30-45 min load followed by 20-80 µg/kg/min Max dose: 2 g/24 hr	PR, QRS, QT interval prolongation, anorexia, nausea, vomiting, rash, fever, agranulocytosis, thrombocytopenia, Coombs-positive hemolytic anemia, SLE, hypotension, exacerbation of periodic paralysis, proarrhythmia	Toxicity increased by amiodarone and cimetidine	4-8 µg/mL With NAPA <40 µg/mL
Disopyramide	SVT, atrial fibrillation, atrial flutter	Oral: <2 yr: 20-30 mg/kg/24 hr divided q6h or q12h (long-acting form); 2-10 yr: 9-24 mg/kg/24 hr divide q6h or q12h (long-acting form); 11 yr: 5-13 mg/kg/24 hr divided q6h or q12h (long-acting) Max dose: 1.2 g/24 hr	Anticholinergic effects, urinary retention, blurred vision, dry mouth, QT and QRS prolongation, hepatic toxicity, negative inotropic effects, agranulocytosis, psychosis, hypoglycemia, proarrhythmia		2-5 µg/ml
CLASS IB: INHIBITS NA$^+$ FAST CHANNEL, SHORTENS REPOLARIZATION					
Lidocaine	VT, VF	IV: 1 mg/kg repeat q 5 min 2 times followed by 20-50 µg/kg/min (max dose: 3 mg/kg)	CNS effects, confusion, convulsions, high grade AV block, asystole, coma, paresthesias, respiratory failure	Propranolol, cimetidine, increases toxicity	1-5 µg/mL
Mexiletine	VT	Oral: 6-15 mg/kg/24 hr divided q8h	GI upset, skin rash, neurologic	Cimetidine	0.8-2 µg/mL
Phenytoin	Digitalis intoxication	Oral: 3-6 mg/kg/24 hr divided q12h Max dose: 600 mg IV: 10-15 mg/kg over 1 hr load	Rash, gingival hyperplasia, ataxia, lethargy, vertigo, tremor, macrocytic anemia, bradycardia with rapid push	Amiodarone, oral anticoagulants, cimetidine, nifedipine, disopyramide, increase toxicity	10-20 µg/mL
CLASS IC: INHIBITS NA$^+$ CHANNEL					
Flecainide	SVT, atrial tachycardia, VT	Oral: 6.7-9.5 mg/kg/24 hr divided q8h In older children, 50-200 mg/m^2/day divided q12h	Blurred vision, nausea, decrease in contractility, proarrhythmia	Amiodarone increases toxicity	0.2-1 µg/mL
Propafenone	SVT, atrial tachycardia, atrial fibrillation, VT	Oral: 150-300 mg/m^2/24 hr divided q6h	Hypotension, decreased contractility, hepatic toxicity, paresthesia, headache, proarrhythmia	Increases digoxin levels	0.2-1 µg/mL

Continued

Table 435-1 Antiarrhythmic Drugs Commonly Used in Pediatric Patients, by Class—cont'd

DRUG	INDICATIONS	DOSING	SIDE EFFECTS	DRUG INTERACTIONS	DRUG LEVEL
CLASS II: β-BLOCKERS					
Propranolol	SVT, long QT	Oral: 1-4 mg/kg/24 hr divided q6h Max dose 60 mg/24 hr IV: 0.1-0.15 mg/kg over 5 min Max IV dose: 10 mg	Bradycardia, loss of concentration, school performance problems bronchospasm, hypoglycemia, hypotension, heart block, CHF	Coadministration with disopyramide, flecainide or verapamil may decrease ventricular function	
Atenolol	SVT	Oral: 0.5-1 mg/kg/24 hr once daily or divided q12h	Bradycardia, loss of concentration, school performance problems	Coadministration with disopyramide, flecainide or verapamil may decrease ventricular function	
Nadolol	SVT, long QT	Oral: 1-2 mg/kg/24 hr given once daily	Bradycardia, loss of concentration, school performance problems bronchospasm, hypoglycemia, hypotension, heart block, CHF	Coadministration with disopyramide, flecainide or verapamil may decrease ventricular function	
CLASS III: PROLONGS REPOLARIZATION					
Amiodarone	SVT, JET, VT	Oral: 10 mg/kg/24 hr in 1-2 divided doses for 4-14 days; reduce to 5 mg/kg/24 hr for several weeks; if no recurrence, reduce to 2.5 mg/kg/24 hr IV: 2.5-5 mg/kg over 30-60 min, may repeat 3 times, then 2-10 mg/kg/24 hr continuous infusion	Hypothyroidism or hyperthyroidism, elevated triglycerides, hepatic toxicity, pulmonary fibrosis	Digoxin (increases levels), flecainide, procainamide, quinidine, warfarin, phenytoin	0.5-2.5 mg/L
CLASS IV AND MISCELLANEOUS MEDICATIONS					
Digoxin	SVT (not WPW), atrial flutter, atrial fibrillation	Oral/load instructions: Premature: 20 µg/kg Newborn: 30 µg/kg >6 mo: 40 µg/kg Give ½ total dose followed by ¼ q8-12h × 2 doses Maintenance: 10 µg/kg/24 hr divide q12h Max dose: 0.5 mg IV: ¾ PO dose Max dose: 0.5 mg	PAC, PVC, bradycardia, AV block, nausea, vomiting, anorexia, prolongs PR interval	Quinidine Amiodarone, verapamil, increase digoxin levels	1-2 mg/mL
Verapamil	SVT (not WPW)	Oral: 2-7 mg/kg/24 hr divided q8h Max dose: 480 mg IV: 0.1-0.2 mg/kg q 20 min × 2 doses Max dose: 5-10 mg	Bradycardia, asystole, high degree AV block, PR prolongation, hypotension, CHF	Use with β-blocker or disopyramide exacerbates CHF, increases digoxin level and toxicity	
Adenosine	SVT	IV: 50-300 µg/kg by need rapid IV push Begin with 50 µg/kg and increase by 50-100 µg/kg/dose Max dose: 18 mg	Chest pain, flushing, dyspnea, bronchospasm, atrial fibrillation, bradycardia, asystole		

AV, atrioventricular; CHF, congestive heart failure; CNS, central nervous systems; GI, gastrointestinal; IV, intravenous; JET, junctional ectopic tachycardia; NAPA, *N*-acetyl procainamide; PAC, premature atrial contraction; PTT, partial thromboplastin time; PVC, premature ventricular contraction; SLE, systemic lupus erythematosus–like illness; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia; WPW, Wolff-Parkinson-White syndrome.

435.2 Sinus Arrhythmias and Extrasystoles

George F. Van Hare

Phasic sinus arrhythmia represents a normal physiologic variation in impulse discharges from the sinus node related to respirations. The heart rate slows during expiration and accelerates during inspiration. Occasionally, if the sinus rate becomes slow enough, an escape beat arises from the atrioventricular (AV) junction region (Fig. 435-1). Normal phasic sinus arrhythmia is caused by the activity of the parasympathetic nervous system and can be quite prominent in healthy children. It may mimic frequent premature contractions, but the relationship to the phases of respiration can be appreciated with careful auscultation. Drugs that increase vagal tone, such as digoxin, may exaggerate sinus arrhythmia; it is usually abolished by exercise. Other irregularities in sinus rhythm, especially bradycardia associated with periodic apnea are commonly seen in premature infants.

Sinus bradycardia is a result of slow discharge of impulses from the sinus node, the heart's natural pacemaker. A sinus rate <90 beats/min in neonates and <60 beats/min in older children is considered to be sinus bradycardia. It is commonly seen in well-trained athletes; in healthy individuals, it is generally without significance. Sinus bradycardia may occur in systemic disease (hypothyroidism or anorexia nervosa), and it resolves when the disorder is under control. It may also be seen in association with conditions in which there is high vagal tone, such as gastrointestinal obstruction or intracranial processes. Low birthweight infants display great variation in sinus rate. Sinus bradycardia is common in these infants in conjunction with apnea, and may be associated with junctional escape beats. Premature atrial contractions are also frequent. These rhythm changes, especially bradycardia, appear more commonly during sleep and are not associated with symptoms. Usually, no therapy is necessary.

Wandering atrial pacemaker (Fig. 435-2) is defined as an intermittent shift in the pacemaker of the heart from the sinus node to another part of the atrium. It is not uncommon in childhood and usually represents a normal variant; it may also be seen in association with sinus bradycardia in which the shift in atrial focus is an escape phenomenon.

Extrasystoles are produced by the premature discharge of an ectopic focus that may be situated in the atrium, the AV junction, or the ventricle. Usually, isolated extrasystoles are of no clinical or prognostic significance. Under certain circumstances, however, premature beats may be caused by organic heart disease (inflammation, ischemia, fibrosis) or drug toxicity.

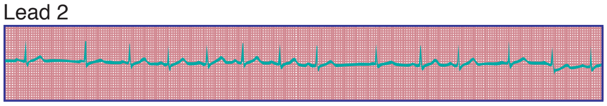

Figure 435-1 Phasic sinus arrhythmia with a junctional escape beat. Note the variation in P-P interval with no significant change in P-wave morphology or PR interval. When the sinus rate is slow enough, the atrioventricular junction takes over and produces escape beats. This rhythm is normal.

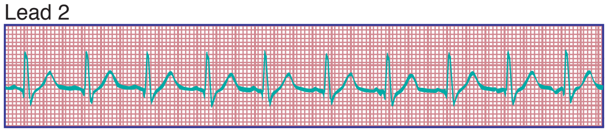

Figure 435-2 Wandering atrial pacemaker. Note the change in P-wave configuration in the 7th, 9th, and 10th beats. The 7th P wave may represent a fusion between the sinus P and the ectopic atrial pacemaker seen in the 10th beat.

Premature atrial contractions are common in childhood, usually in the absence of cardiac disease. Depending on the degree of prematurity of the beat (coupling interval) and the preceding R-R interval (cycle length), premature atrial complexes may result in a normal, a prolonged (aberrancy), or an absent (blocked premature atrial complex) QRS complex. The last occurs when the premature impulse cannot conduct to the ventricle due to refractoriness of the AV node or distal conducting system (Fig. 435-3). Atrial extrasystoles must be distinguished from premature ventricular contractions (PVCs). Careful scrutiny of the electrocardiogram for a premature P wave preceding the QRS will either show a premature P wave superimposed on, and deforming, the preceding T wave, or a P wave that is premature and has a different contour from that of the other sinus P waves. Atrial premature complexes usually reset the sinus node pacemaker, leading to an incomplete compensatory pause, but this feature is not regarded as a reliable means of differentiating atrial from ventricular premature complexes in children.

PVCs may arise in any region of the ventricles. They are characterized by premature, widened, bizarre QRS complexes that are not preceded by a premature P wave (Fig. 435-4). When all premature beats have identical contours, they are classified as uniform, suggesting origin from a common site. When PVCs vary in contour, they are designated as multiform, suggesting origin from more than one ventricular site. Ventricular extrasystoles are often, but not always, followed by a full compensatory pause. The presence of fusion beats, that is, complexes with morphologic features that are intermediate between those of normal sinus beats and those of PVCs, proves the ventricular origin of the premature beat. Extrasystoles produce a smaller stroke and pulse volume than normal and, if quite premature, may not be audible with a stethoscope or palpable at the radial pulse. When frequent, extrasystoles may assume a definite rhythm, for example, alternating with normal beats **(bigeminy)** or occurring after 2 normal beats **(trigeminy).** Most patients are unaware of single PVCs, although some may be aware of a "skipped beat" over the precordium. This sensation is caused by the increased stroke volume of the normal beat after a compensatory pause. Anxiety, a febrile illness, or ingestion of various drugs or stimulants may exacerbate PVCs.
